Keywords

Amplicon
The region of a target sequence that is amplified during the PCR, encompassing the sequence bounded by and including the two primer sequences.

Baseline
The range of early PCR cycles that contain low levels of increasing fluorescent signal that is undetectable over the baseline fluorescence of the reporter dye.

Fluorescence Resonance Energy Transfer
Light energy transferred from an excited dye to a neighboring dye in close proximity, resulting in the quenching of the visible emission of light from the primary dye.

Polymerase Chain Reaction
Primer-directed geometric increase in a DNA template using a thermostable DNA polymerase, necessary reagents, and a succession of heating and cooling steps performed in a thermocycling device.

Real-time PCR
This is the continuous collection of fluorescent signals from one or more polymerase chain reactions. Quantitative real-time PCR is the conversion of the fluorescent signal from each reaction to a numerical value for each sample. This is accomplished by calculation from a known reference sample (ddCt) or interpolation from a quantified standard curve. Real-time PCR is the most sensitive and accurate method for the detection and accurate quantification of nucleic acids from any biological source. The term real-time PCR in this article refers to both PCR and RT-PCR.

Reverse Transcription
The primer-directed synthesis of a DNA copy (cDNA) using RNA as the template and reverse transcriptase.

Threshold
A level of fluorescent signal that is significantly above the baseline fluorescence level. The threshold is set by the software or manually by the user within the geometric phase of the amplification curve and is used to define the cycle threshold (Ct) or crossing point (Cp).

Transcript quantification methodology has evolved from Northern blots to RNase protection to competitive RT-PCR. Each of these methods made strides toward greater sensitivity and accuracy in quantification. Since the introduction of the 7700 Sequence Detection System and Taqman® chemistry by Applied Biosystems in 1996, quantitative real-time PCR has become widely accepted as the most sensitive and accurate method for the quantification of both RNA and DNA from a wide variety of sources. Today, there are a number of real-time instruments from a variety of vendors and several detection methodologies and kit chemistries available. At the same time, prices for real-time platforms are falling dramatically. This trend means that the technology is moving from one found primarily in core laboratories to the bench tops of individual investigators.

There are several ways to interrogate a cell for changes induced by artificial or natural agents during a biological process. One way is to look for changes in cellular transcript levels that may indicate downstream changes in the corresponding protein. In another instance, the focus may be on the presence or absence of a viral or bacterial pathogen. In this case, detecting not only the presence but also the degree of infection provides valuable information. Alternatively, looking for the presence or the level of expression from a transgene or the inhibition of expression of an endogenous gene by an RNAi agent may be the question of interest. In all cases, quantitative real-time PCR technology can be utilized to provide the required results. However, successful implementation of the technology requires the user to have a basic background in the theoretical principles of real-time PCR as well as their practical application. The goal of this review is to provide this information.

It will not be possible to cover all aspects of real-time PCR in this review. For a more comprehensive overview of real-time PCR, ''A-Z of Quantitative PCR,'' edited by Stephen Bustin, is highly recommended.

1 Real-time PCR Basics

Before any meaningful discussion of real-time PCR can be initiated, it will be useful to discuss the theoretical principles governing and basic chemistries utilized in real-time PCR.

1.1 Principles of Real-time PCR

Prior to real-time PCR, the effect of the primers and other components of the reagent chemistry on the amplification process during the polymerase chain reaction was something of a black box.

Tubes bearing assay chemistry, primers, and template were exposed to 30 or more cycles of heating and cooling on a thermocycler. The reaction product(s) were then separated on a gel. The presence of a single band of the correct size with any magnitude was deemed a successful experiment. With the advent of real-time PCR, the ability to observe the status of the reaction products during every cycle has brought new insight into the kinetics of template amplification. Most real-time PCR experiments are run for 40 cycles to capture the complete amplification profile from every tube or well. In an ideal PCR, the increase in template occurs geometrically throughout the entire 40 cycles. However, we now know that this is not the case. The amplification of any template can be defined by four phases: (1) the baseline; (2) the true geometric phase; (3) a linear phase as the efficiency of the PCR starts to fall in each successive cycle; and (4) a plateau as amplification arrests (Fig. 1). All three phases can be seen in the amplification plots from any real-time PCR reaction. An example of amplification curves from a 5-log dilution series of an oligonucleotide standard can be see in Fig. 2. Why the PCR slows down and then stops is not clear, but may be due to the build up of products that are inhibitory to the reaction. One thing that is clear is that the concentration of all reactants is in vast excess and none of them should be depleted during 40 cycles of PCR.

Samples with very high amounts of template have been observed, using real-time PCR, to stop amplification sooner and with fewer end products than those with lower initial template concentrations. The result is that the one with higher template will appear to have less band intensity on a gel compared to the one with

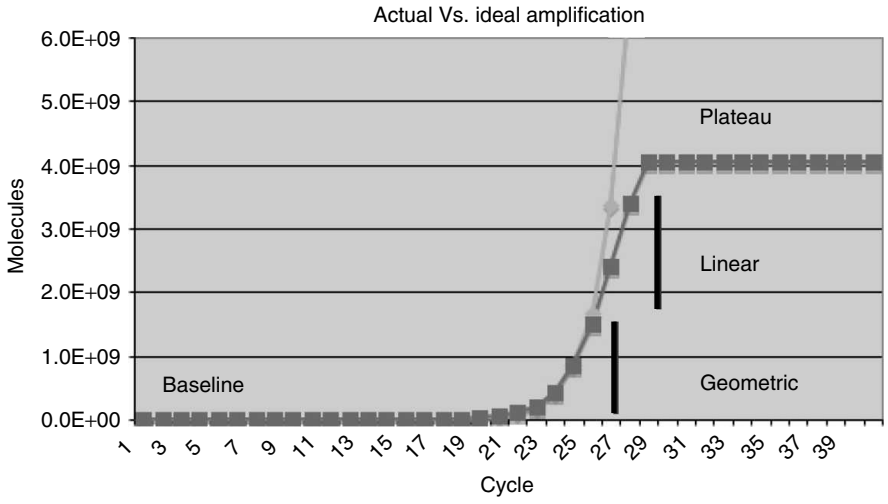

Fig. 1 Graphical representation of the fluorescent signals from an ideal versus an actual reaction over 40 cycles of real-time PCR. In an ideal PCR, there are two phases, a baseline where the signal is below the level of detection followed by a geometric increase in fluorescence that continues over the remaining cycles. However, in an actual reaction, there are four phases. As in the ideal reaction, there is a baseline followed by a geometric phase. However, the amplification becomes less than ideal, leading to a linear phase and finally a plateau where no further increase in signal occurs over the remaining signals.

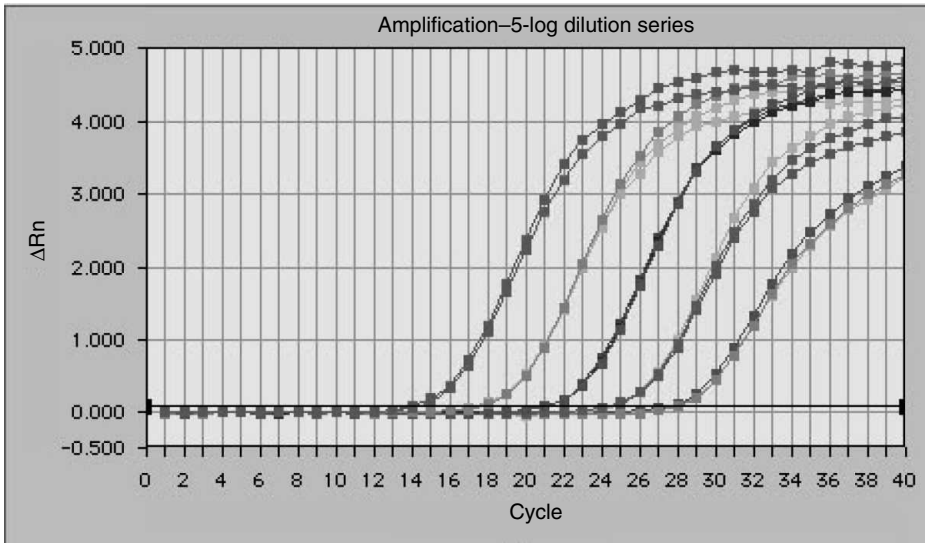

Fig. 2 Dilution curves from a real-time PCR experiment illustrating the four phases of a polymerase chain reaction. Amplification curves from a 5-log standard curve illustrating the four phases of signal generation in real-time PCR: baseline, signal being made, but not detectable by the instrument; geometric, detectable signal with maximal PCR efficiency; linear, postgeometric with slowly declining PCR efficiency; and plateau, no or very little new product made.

significantly lower template concentration after 30 or more cycles of PCR. Therefore, the only way to use the polymerase chain reaction for quantitative measurements is to compare samples in the early, geometric part of their amplification curves where the true differences in the samples can be detected. The ability to do so is what allows real-time PCR to be a *bona fide* quantitative technique.

1.2 The Reverse Transcription Reaction

Quantification of RNA begins with the reverse transcription reaction, which converts the RNA into a complementary DNA sequence or cDNA (also known as "copy DNA"). Two viral reverse transcriptase (RT) enzymes, used to make cDNA, are commercially available: AMV-RT from avian myeloblastosis virus and MMLV-RT from Moloney murine leukemia virus. AMV is a dimeric protein, while MMLV is a monomer. Both enzymes have RNase H activity, the ability to cleave RNA in a RNA/DNA hybrid. However, the activity in AMV-RT is much higher than that in MMLV-RT. This activity can be separated from the reverse transcriptase activity by site-directed mutagenesis. AMV-RT is a more processive enzyme (incorporates more nucleotides per unit time on the template) and is active at higher temperatures than MMLV-RT (42 °C vs. 37 °C for wild-type enzymes). Cloned variants of these enzymes have pushed the temperature limits to 58 °C for AMV-RT and 55 °C for MMLV-RT. Although both have been used for real-time PCR, MMLV-RT works best in practice, which is not consistent with the above characteristics. Both

enzymes are inhibitory to the PCR. The inhibition is enzyme concentration dependent. For this reason, it is important to keep the amount of reverse transcriptase as low as possible and still produce cDNA with 100% efficiency. The exact mechanism for the inhibition is not known. It has been proposed that although the high melting temperature of the PCR kills the reverse transcriptase activity, the DNA binding capacity of the enzyme may persist, forming a physical barrier that affects the activity of *Taq* polymerase. The higher temperature stability, dimeric structure, and greater RNase H activity of AMV-RT, may contribute to greater PCR inhibition than the MMLV-RT enzyme.

One major issue for RT-PCR is what primer to use in the reverse transcriptase reaction? The classic primer for cDNA library and standard RT-PCR has been oligo-dT, an oligonucleotide with 18 to 20 dT residues. Since most (roughly 95%) messenger RNA found in higher eukaryotes have poly-A tails at their 3′ ends, the oligo-dT will initiate cDNA synthesis utilizing mRNA molecules, but not rRNA or tRNAs. There are, however, two flaws in this approach for real-time quantitative PCR. The first is that long poly-A sequence stretches exist within mRNAs as well within some of the other RNA classes and these sites will initiate cDNA synthesis as well. Most important, however, is the fact that not all real-time PCR assays are targeted at sequences near the 3′ end of the transcript. Some mRNAs are over 15 Kb in length with 3′ untranslated regions (UTRs) that are 4 Kb or more. In a situation where you need to make enough cDNA to make a recombinant bacterial clone, this is not a problem. However, real-time PCR is a quantitative process where every molecule present should be detected for proper comparisons to be made. Priming with oligo-dT alone will not ensure true quantification for every transcript for every assay unless this caveat has been taken into consideration at the time of assay design. Another approach is the use of random primers that can be found as hexamers up to decamers. Random primers are short oligonucleotides that, as a population, contain every possible oligo sequence. Thus, there will be a subpopulation of the correct primer sequence for every 6-mer up to a 10-mer in every target sequence. The frequency with which a random primer will find a complementary sequence in any template is given by the formula 4^x, where x is the length of the primer sequence. For a 6-mer, a perfect match will occur every 4096 bases, while a 10-mer would be approximately every 1.05×10^6 bases. Using random primers, more than one cDNA may be synthesized for each transcript molecule resulting in the whole transcript being made into multiple cDNAs. The rationale is that every transcript in the total RNA population will be converted to cDNA with equal efficiency. However, there is no data to confirm that premise. Further, especially with random hexamers, there is the possibility that a primer will bind within the amplicon sequence resulting in only a partial cDNA, thus making that molecule undetectable in that assay. Keeping these caveats in mind, in practice, random primers can work well and are the method of choice if multiplexed assays are being performed where more than one transcript or gene will be amplified and detected simultaneously within the same reaction vessel. Some investigators hedge their bets and use a combination of both oligo-dT and random primers. For single-assay reactions, however, there is a third choice. That is to use an assay-specific primer. That is, the same primer that will

be used as the reverse primer in the following real-time PCR. This method will make, in theory, cDNA from every possible RNA template for that assay in precisely the correct location required for the following PCR. Unlike when oligo-dT or random primers have been used, the complexity of the resulting cDNA population is significantly lower when using an assay-specific primer. This means that the number of inappropriate priming events that could potentially occur during the PCR will be greatly reduced. Unlike when oligo-dT is used as a primer restricting the assayable region to the 3′-end of the message, use of assay-specific primers allows the amplified region of the assay to lie in any part of the transcript. As an aside, it should be mentioned that RNA can form complex structures resulting in self-priming and extra-assay cDNA synthesis even in the absence of any exogenous primer.

1.3 The Polymerase Chain Reaction

It is hard to think of another laboratory technique that has come along in our time that has had a more dramatic impact on scientific knowledge over such a broad range of subjects than the PCR. Real-time PCR has extended the sensitivity and specificity of nucleic acid detection greatly beyond what was available previously. The component that makes the polymerase chain reaction possible was the discovery of thermostable DNA polymerases that could withstand the multiple cycles of heating required to melt long DNA duplexes and cooling to temperature optimal for the succeeding polymerization steps. The first enzyme, and still the most commonly used, is *Taq* DNA polymerase from *Thermus aquaticus*. *Taq* is still one of the most processive thermostable enzymes commercially available. Most members of *Thermus* sp. also have a 5′-exonuclease activity that is required for cleavage of certain dual-labeled probes required for signaling.

There are two functional types of *Taq* commercially available, wild type and hot start. Hot-start enzymes are similar to their non-hot-start counterparts, but they have been reversibly inactivated by, (1) a heat activated mutation; (2) a small molecule; or (3) one or more antibodies directed at the active site of the enzyme. As the name implies, it is necessary to heat hot-start enzymes for their activation. The time varies greatly for enzyme activation with a minute at 94 to 95 °C being sufficient for the antibody inactivated enzymes while, 10 or more minutes at high temperature are necessary for mutated or chemically inactivated enzymes. All of these transient inhibition mechanisms are effective in repressing enzymatic activity until the initial melting step.

To fully appreciate the difference between using a hot-start *Taq* and non-hot-start *Taq*, you have to understand what happens to the targeted DNA sequence during the PCR. The most important part of the PCR is the first two cycles. During the first cycle, single-stranded cDNA or viral DNA is made into a double-stranded DNA molecule facilitated by new strand synthesis initiated from the forward primer in the reaction mix. Therefore, true amplification does not begin until the second PCR cycle for single-stranded templates. For a double-stranded DNA template, amplification begins during the first PCR cycle because both primers have a template. Nonspecific bands due to inappropriate priming events (false priming) occur during the first cycle of the PCR. This is true for single- or double-stranded

templates. This can occur because the reaction starts at a low temperature prior to reaching the first melting step of the PCR cycle, usually 94 to 95 °C. It is during this initial warming of the reaction mixture that false priming and extension by the DNA polymerase can occur. Thus, the use of a hot-start *Taq* that requires 1 to 10 min at 94 to 95 °C for activation will not be active in the lower temperature range during the first cycle of the PCR. For the remaining cycles of the PCR, the lowest temperature is the annealing temperature, usually 50 to 60 °C, depending on the T_m (melting temperature) of the primers. At this elevated temperature, false priming is much less likely to occur.

2
Fluorescent Dyes, Assay Chemistries, and Real-time Instruments

Real-time PCR has evolved from a single instrument that utilized one detection assay and two dyes for signaling to a large number of instruments, with a variety of assay chemistries and fluorescent dyes available. To fully comprehend how real-time PCR works, it is necessary to have a basic understanding of fluorescence and how different assay chemistries and real-time instruments work.

2.1
Fluorescence in Real-time PCR

All real-time instruments are based on the real-time detection of an increasing fluorescent signal over the length of an experiment. The increase in fluorescent signal detected is directly proportional to the corresponding increase in the number of template molecules made during amplification. It is this principle that makes fluorescence useful for quantitative real-time PCR as a detection mechanism.

Fluorescent compounds absorb light as photons within a narrow, optimal wavelength. Light at the optimal wavelength is called the excitation wavelength. When a fluorescent molecule absorbs a quantum of light, the molecule is boosted to a higher energy state. This higher energy state is transient and short lived. This higher energy state decays, falls back to the ground state, and light is given off. This form of emission is called fluorescence. The emitted light is necessarily at a longer wavelength than the initial excitation wavelength. This shift in wavelength is called a Stoke's shift. For every fluorescent dye, there is an optimal absorbance or excitation wavelength and an optimal, shifted emission wavelength used for detection.

Having a steady state fluorescent signal throughout the PCR would not be useful. What is required is a very low initial signal that increases in proportion to the products made during the PCR to a high level that is easily detectable. One way to achieve this kind of signal production is to take advantage of the principle of fluorescence resonance energy transfer or FRET. During FRET, one dye acts as a donor and the other as the acceptor. The excited donor dye transfers its emission energy to the second dye, and that energy is used to excite the electrons in the second dye. The excited acceptor dye then emits light at its emission wavelength which can then be detected. Under conditions of FRET, the light emitted from the donor dye is quenched. The efficiency of energy transfer between the two dyes falls as the 6th power base 10 of the distance between the dye molecules. Therefore, the donor and acceptor molecules have to be in close proximity (10–100 Å). Table 1 shows a list

Tab. 1 Common dyes used in real-time PCR.

Dye name	*Max. Ab [nM]*	*Max. Em [nM]*
DABCYL	453	None
Fluorescein™	492	520
6-FAM™	494	518
JOE™	520	548
TET™	521	536
Yakima Yellow™	526	448
BHQ1™	534	None
HEX™	535	556
VIC™	538	554
Cy3™	552	570
TAMRA™	565	580
ROX™	585	605
LightCycler640™	625	640
Cy5™	643	667
LightCycler705™	685	705

of the most common dyes used in real-time PCR.

There are three classes of fluorescent dyes used in real-time PCR based on their function: (1) the reporter, which is the dye monitored during the experiment; (2) the quencher, the dye responsible for quenching the reporter signal in FRET-based assays; and (3) the reference, a dye common to all reaction vessels used to normalize the signal.

- *Reporter dyes:* the most used reporter dye is 6-FAM, a fluorescein derivative with a green emission. This dye can be efficiently excited by the argon laser found in the initial real-time machines (see the following) and has remained as the reporter dye of choice of many chemistries in use today. The first multiplexing experiments, running two or more assays simultaneously in the same reaction, were done with laser-based instruments. For this reason, other fluorescein derivatives with progressively longer excitation wavelengths were made available. The instruments available today can utilize a much wider variety of reporter dyes, from the green through the red spectrum. Another reporter dye in wide use is SYBR Green I that has very low fluorescence as a free dye, but increases dramatically when bound to double-stranded DNA. The number of dyes now on the market that are suitable for use as reporters is continuing to increase.
- *Quencher dyes:* when FRET is used as the signaling mechanism, the fluorescence of the reporter dye is quenched by a neighboring dye. There is at least one exception to this rule and that will be discussed below. There are two classes of quencher dyes; those that emit light and those that do not. The initial FRET pair was 6-FAM and TAMRA, a rhodamine derivative that emits light in the red spectrum. The FAM/TAMRA combination works very well, but TAMRA is sensitive to the alkaline hydrolysis step used to remove oligonucleotides from the solid support used for their synthesis. The result is a comparatively low yield of functional FAM/TAMRA molecules at the same or higher cost compared to a FAM/dark dye oligonucleotide. The dark dyes represent the second class of quenchers. As the name implies, no light is emitted from these dyes although they work very well as quenchers and are available for a large spectrum of reporter dyes. The initial dark dye was DABSYL and is used today when a high degree of quenching is not desired when the reporter and quencher are transiently separated. An example is a molecular beacon (see the following). A second generation of dark dyes is the black hole quenchers or BHQs. As the name implies, these dyes are very efficient quenchers and emit no light. There are three different variants of these dyes available, BHQ1, 2, and 3.

The higher the number, the more red-shifted the reporter dye used in a FRET pair. BHQ dyes are particularly effective when maximal quenching is desired. An example would be Taqman® probes (see the following).

- *Reference dyes:* All real-time PCR instruments have the capability of monitoring multiple reactions during the course of an experiment. It is important that the signal from each reaction vessel be the same so that the results can be compared. One way to achieve this is to include a reference dye in the reaction mix. The most commonly used reference dye is ROX, a red dye that is well shifted from 6-FAM. In practice, any dye can be used as a reference dye as long as it doesn't significantly spectrally overlap the reporter dye(s) in the reaction. Not every instrument requires the presence of a reference dye in the reaction. This will be discussed in the following text. However, signal normalization is a part of the data analysis of all real-time PCR software packages.

2.2 Real-time Instruments

There are three major components in every real-time PCR instrument: (1) the light source; (2) the light gathering and detection system; and (3) the thermocycler. Although each real-time platform is designed to measure a fluorescent signal from the same fluorescent dyes, the way each instrument excites and detects those dyes can be quite distinct. The mechanism driving the heating and cooling cycles can also vary. These differences are driven partially by patent issues and also by an on-going desire to build a more compact, less expensive instrument that delivers comparable or better performance when compared to earlier models. A basic understanding of how real-time PCR instruments work is important for fully understanding how the data is produced.

Light Sources: All the assays currently in use utilize fluorescent dyes as a read out. Therefore, the light source has to illuminate the fluorescent dye in use near its optimum excitation wavelength. There are three different types of light sources in use today: lasers, quartz halogen-tungsten lamps, and light emitting diodes (LEDs).

Lasers emit light that is coherent, monochromatic, and directional. The only two real-time platforms to use a laser are the Applied Biosystems 7700, still widely used but no longer manufactured, and the 7900. Both use an argon laser that emits light at 488 nm. The advantage of a laser is the light is monochromatic and intense. The disadvantage is the reporter dyes used have to have an excitation maximum near 488 nM. Argon lasers work well for fluorescein dyes attached to oligonucleotides such as 6-FAM or the free dye SYBR Green I. However, as the excitation wavelength for a reporter dye moves toward the red spectrum argon lasers lose their ability to excite the dye.

Quartz halogen-tungsten lamps are capable of emitting a steady beam of light from 350 nm to over 2000 nm and are sometimes referred to as ''white light'' sources. For this reason, a filter must be employed that only allows a narrow band of light at or close to the optimal excitation wavelength for a particular fluorescent dye. Most machines with quartz halogen-tungsten light sources have 4 or 5 filter sets to include a broad range of dyes with excitation maxima distributed over the green–red spectrum.

Light emitting diodes or LEDs are semiconductors that emit light within a narrow bandwidth, usually 30 to 40 nm, when stimulated by an electric current. Rather than using filters, as mentioned earlier, one or more LEDs are used that emit light at increasingly longer wavelengths to match the desired excitation maxima of the reporter dye. Thus, for every dye that has a significantly different excitation wavelength, a matching LED for the new wavelength must be present. The light from most LEDs does not have the light intensity of a laser or even a quartz-halogen bulb, but there is very little heat generated during their use and they require less power to operate.

Real-time Instruments: – The following is a description of the light path in three different real-time instruments. Each one is an example of a machine that utilizes one of the three light sources described above. Although the majority of the new instruments on the market use quartz halogen-tungsten lamps, there are still those on the market that use LEDs or a laser as a light source.

The Applied Biosystems 7900HT – This is the only machine available in the market today that uses a laser light source. However, it is also the only machine that can use either 96- or 384-well plates. It may well be that the high intensity of the laser light source is required for the excitation of reporters in 384 wells. The laser emits light at 488 nm that is directed at a beam splitter that redirects the light over a scan head with 16 lenses, sitting just above the plate in the heated cover. The lenses focus the light into either 8 or 16 wells at a time, depending on which plate is in the instrument. The emitted light comes back up through the lenses and passes through a dichroic mirror that deflects the individual beams of emitted light onto a CCD camera for detection. The scan head goes down each column of the plate, using a stepper motor, and collects the emitted light from the entire plate. The scan head returns to the first column and a new scan ensues until all the cycles have been completed. Multiple scans are made for each column during the melting and annealing/extension phases of each cycle. The plate rests in a metal block that is heated and cooled by a Peltier thermocycler. Thermocyclers, based on the Peltier principle, utilize electron flow to heat and cool the metal block rather than a conventional heater unit opposed by a cooling device.

The Roche Lightcycler and Lightcycler2 – These instruments use a single blue LED light source in an optical range similar to the argon laser. The Lightcyclers have a 32-sample capacity. Each reaction chemistry is contained within a thin capillary tube, which results in a high surface to volume ratio. Cycling times in the Lightcycler units are much reduced because heated air is used instead of a metal block for heating and cooling. This is due to the excellent heat transfer possible using capillary tubes. The samples spin past the light source like tubes in a centrifuge using a stepper motor. The excitation light goes through each tube in sequence and the emitted light is focused on the capillary tip, goes through a dichroic mirror, and is then read by either 3 (Lightcycler) or 6 (Lightcycler 2) photo detection diodes, each specific for an increasing and narrow wavelength range.

The Stratagene Mx3000p – This instrument utilizes a quartz tungsten-halogen (white light) source. The excitation range is from 350 to 750 nm with a similar detection range. Excitation and emission wavelengths are selected using filter pairs

specific for each reporter dye to be detected. Light passes through an excitation filter into a fiberoptic cable and into the well of a 96-well plate. The emitted light passes back up the fiberoptic cable through an emission band pass filter and onto a photomultiplier tube (PMT) for detection. The plate is scanned once for each fluorescent dye with the filter wheels moving in tandem to bring the new filter pair into the optical path. The thermocycler is a combination of Peltier, convection, and resistive technologies unique to the Stratagene machines that results in uniform temperatures across the block. The Stratagene Mx3000p is just one example of many instruments on the market that use a quartz halogen-tungsten light source.

2.3 Selected Assay Chemistries

Just as understanding the mechanical workings of the real-time detector being used are important, knowing the principles underlying the fluorescent signaling system utilized in an assay are equally important. There are three mechanisms used to generate a fluorescent signal utilized in the large variety of assay chemistries available for real-time PCR. First is the binding of a free fluorescent dye to the newly amplified double-stranded DNA, second is a fluorescent dye that is associated with one of the PCR primers that generates a signal when incorporated into the amplified product, and third are fluorescently labeled oligonucleotides, independent of the primers called probes, that bear the fluorescent signal. There are three probe types and the method of signaling is different for each of them. In all of these assay types, the signaling molecule has to have a very low initial fluorescence that increases in direct proportion to the amount of DNA made during the PCR. Except for the intercalating dyes, all the other chemistries available depend on FRET.

SYBR Green I – The simplest assay mechanism involves the incorporation of a free dye into double-stranded DNA as it is synthesized (Fig. 3). SYBR Green I

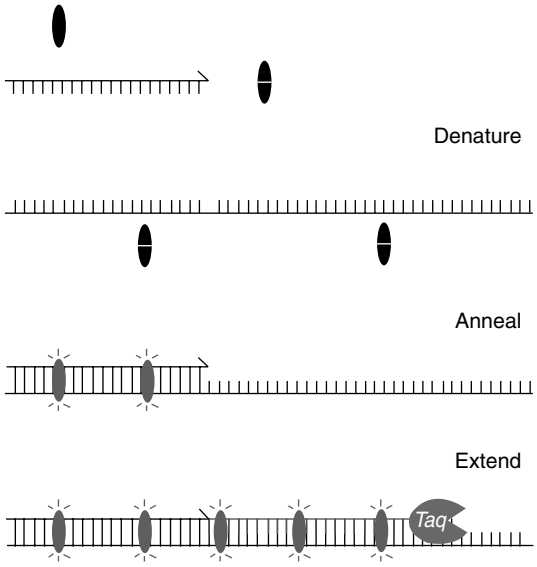

Fig. 3 Graphical representation of SYBR Green I in fluorescent signal generation during a PCR. Free dye has very low fluorescence and will not bind to single-stranded, denatured DNA. During primer annealing, a double-stranded structure is formed and SYBR green dye begins to bind and emit a fluorescent signal. During primer extension by *Taq* DNA polymerase, the number of SYBR green dye molecules bound per double-stranded molecule and the fluorescent signal increases proportionally. The process is repeated in each cycle with increasing total fluorescence (see color plate p. xxxiv).

has a very low fluorescent signal when in solution as a free dye and a low affinity for single-stranded nucleic acids at the concentration used for real-time PCR. The latter characteristic is important, as a high affinity for single-stranded DNA would be inhibitory to the progression of the PCR. Following the synthesis of double-stranded DNA, the dye binds to the minor groove and a dramatic increase in fluorescent signal can be detected. Initially, dyes such as ethidium bromide were used for this purpose. However, ethidium bromide has a relatively high signal as free dye, has a higher affinity for single-stranded DNA, and the increase in fluorescence over background following binding is fivefold lower than SYBR Green I. The positive aspects of using a dye-based real-time assay are as follows: (1) SYBR Green I is a relatively low cost signaling molecule; (2) only one dye is required for all assays; and (3) assay design is limited to two simple primers. The negative aspects of a dye-based assay are as follows: (1) lower specificity as all double-stranded DNA molecules made during the PCR will make a signal; (2) setting up a new assay requires running the initial products on a real-time instrument as well as a DNA acrylamide gel to check for nonspecific amplification products and primer dimers that can add a false signal, in the case of the former, and increased assay background noise from the latter; and (3) the use of a more expensive hot-start *Taq* is a must to reduce inappropriate priming events that can occur at sites with similar complementary sequences during the initial PCR cycle.

Primer-based signaling assays – As the title implies, the signal is generated by a reporter dye on one of the two primers required for the PCR. There are many imaginative reporter–dye primer combinations available that can be used in real-time PCR. Only two will be presented here. These two assay types represent the extremes in the level of complexity found in primer-based signally systems.

1. LUX primers (light upon extension) have a 4 to 6 base extension on the 5′ end of the primer complementary to the internal sequence of the primer that is complementary to the target sequence. A single reporter dye is covalently linked to an internal base near the 3′ end of the primer. The 5′ extended sequence forms a hairpin loop and stem structure within the primer sequence (Fig. 4). When the reporter dye is in close proximity to the double-stranded stem, particularly to guanidines, the signal is quenched without the need for another dye. Guaninidine residues are able to act as quenchers, similar to but not as efficient as an appropriate FRET dye pair. When the primer becomes incorporated into a PCR product, the stem structure is broken and this relieves the quenching of the fluorescent signal. The maximum increase in signal is about 10-fold over background. The advantages of this system are as follows: (1) relatively low cost, only a single dye is required on one of the primers; (2) relatively simple assay design; and (3) can use multiple, assay-specific reporter dyes. The disadvantages are as follows: (1) an acrylamide gel is necessary to determine assay specificity; (2) a hot-start *Taq* is necessary for optimal primer assay fidelity; and (3) it has the lowest signal to background fluorescent signal of any assay.
2. Scorpion primers are named after their mode of binding during the signaling phase and represent the most complex primer-based signaling system. Their advantage is that they have the highest

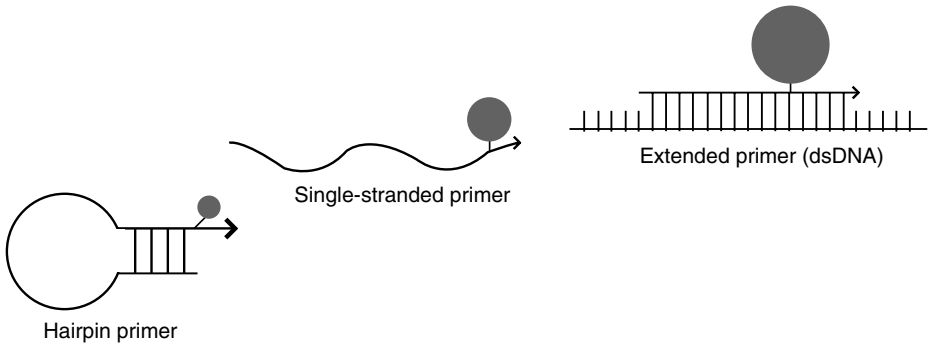

Fig. 4 Structure and mode of action of a LUX primer (light upon extension). LUX primers are inherently quenched because of a designed, short self-complementary sequence added to the 5′ end of the primer. The fluorescent moiety on the 3′ end of the primer is quenched in this confirmation. Following the melting and subsequent annealing phase, the primer binds to complementary sequence on the template and becomes incorporated into the new strand, leading to a significant increase in fluorescence.

template specificity of any primer-based assay. Two variations of the scorpion primer assay have been described, one based on a stem and loop and a newer one based on a linear duplex. Both result in efficient quenching of the reporter signal. The loop version is shown in Fig. 5 and will be described here, but they both have identical fluorescent reporter mechanisms. The basic components of scorpion primers are (1) the actual primer sequence; (2) a PCR stopper moiety to prevent PCR read through; (3) a probe-specific sequence; and (4) a fluorescence detection system comprised of reporter and quencher dyes. The primer structure begins with a standard complementary sequence for the transcript of interest on the 3′ end. Upstream from the primer sequence is the PCR stopper that prevents the upstream sequence from becoming double stranded followed by an internal DABSYL quencher dye. Next comes a stretch of oligonucleotides that can anneal to a complementary internal sequence in the PCR product, followed by 5 to 6 bases of complementary sequence to an internal region just upstream of the DABSYL dye that can form a stem structure bringing the reporter dye at the 5′ end into close proximity to the DABSYL quencher (Fig. 5). The reporter signal is quenched by FRET between the two dyes at the annealing temperature. Detection begins when the 3′ end of the scorpion primer binds to a complementary region of the single-stranded template and is extended during the extension phase. In the next PCR cycle, the resulting DNA duplex and internal stem of the scorpion primer are melted, resulting in a single-stranded molecule with the scorpion reporter incorporated. At the annealing temperature, the internal loop portion of the scorpion primer complementary to a stretch of sequence within the newly synthesized strand can now anneal to the newly made template sequence. The reporter dye is no longer quenched by FRET because the reporter dye is physically distant from the DABSYL and reporter signal

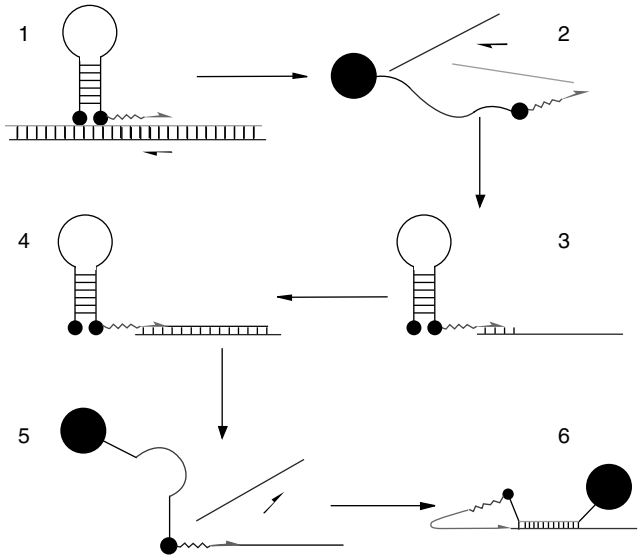

Fig. 5 The complex structure and mechanics of fluorescent signal generation by a scorpion primer. (1) dsDNA template and complete scorpion primer with a FRET quenched reporter dye; (2) melting of template and primer structure transiently releasing FRET quench of reporter dye; (3) template-complementary region of the 3′ end of the primer anneals to ssDNA template; (4) primer extension by *Taq* DNA polymerase; (5) second melting step making the newly made DNA single stranded; (6) internal complementary sequence of the scorpion primer anneals to an internal region of the newly made template releasing the reporter dye to generate a signal.

is detected. The scorpion primer is the only primer-based assay system that has a comparable template specificity to a probe-based assay. It is also the most complex and costly to make.

Probe-based signaling assays – Probe-based assays introduce one or two new oligonucleotides whose sole purpose is to provide the fluorescent signal for the assay. These extra, fluorescently labeled oligonucleotides anneal to a region in the amplicon sequence that lies between, and does not overlap, the two primers. The primers are still the driving force for amplification and they determine the efficiency and sensitivity of the assay. However, with the introduction of the intervening oligonucleotide probe, the primers are no longer the sole determinants of assay specificity. As in primer-based assays, the amplified sequence is determined by the primers alone. However, unlike primer-based assays, fluorescent signal will be realized solely from those amplicons that also have a complementary sequence for the fluorescently labeled probe.

There are three different probe designs in common use and each relies on FRET to either quench or induce the reporter signal. All three of these assay formats have increased specificity over SYBR Green I or simple primer-based systems. This is because both primers and the probe have to anneal to the correct target sequence

and work together as a unit for signaling to occur.

1. Taqman® assays are the original chemistry for real-time PCR first commercialized by Applied Biosystems in 1996 (Fig. 6). The probe consists of a dual-labeled oligonucleotide with a reporter dye on the 5′ end and a strong quencher dye such as a BHQ, on the 3′ end. The probe is designed with a higher T_m than the two primers, usually 8 to 10 °C, to ensure it will bind to the template before the primers as the temperature is lowered from the melting to the annealing setting. When free in solution during the annealing step, the probe is quenched. However, when the probe is able to anneal to a single-stranded complementary region that lies just 3′ to one of the primer binding sites, it is partially dequenched because the reporter and quencher dyes are separated and FRET is much reduced. It is critical that the probe bind to every available template prior to the initiation of primer extension to ensure that they all are detected. As *Taq* DNA polymerase synthesizes a new strand, it displaces and cleaves the probe molecule utilizing an inherent 5′-exonuclease activity within the enzyme that is separate from the polymerase activity. For the most part, only DNA polymerases from *Thermus* sp. (such as *Taq* from *T. aquaticus*) have this 5′

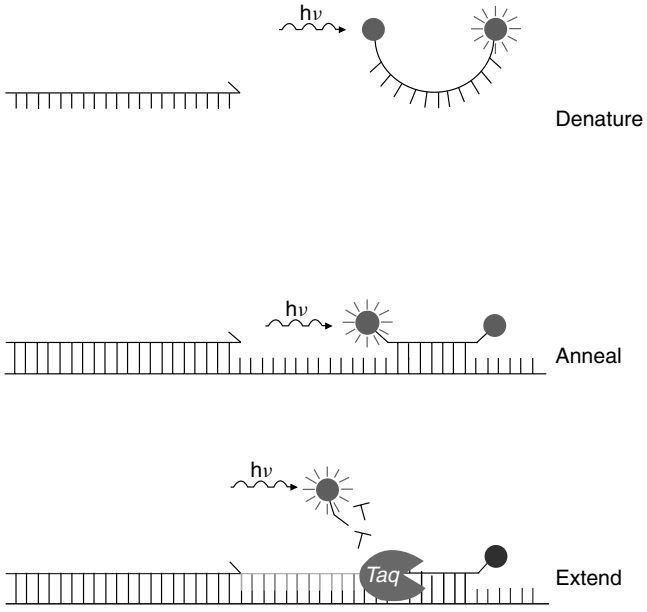

Fig. 6 Graphic showing fluorescent signal generation by a Taqman® probe. When free in solution, the reporter fluorescent dye is quenched by FRET. Owing to a higher T_m, the probe anneals to a complementary template sequence before the primer on the same strand. During primer extension by *Taq* DNA polymerase, the probe is displaced and degraded by a nuclease present in *Taq* DNA polymerase. Release of the reporter dye from the quencher dye allows the full signal to be realized.

nucleotidase activity. Following probe cleavage, the reporter dye is now free in solution and permanently dequenched after being physically removed from the quencher dye. The Taqman name stems from this cleavage step, from the computer game Pac Man.

2. Molecular beacons are similar to Taqman® probes in that they are dual-labeled oligonucleotides having a reporter dye and a DABSYL quencher. Once again, the T_m value of the probe is higher than the two primers to ensure probe binding prior to primer extension. The difference in probe structure, compared to Taqman® probes, is the addition of 4 to 6 extra self-complementary bases on both ends of the probe sequence that do not anneal to the target sequence (Fig. 7). At the annealing temperature of the PCR cycle, this forces the two dyes to come into close proximity with one another when a short stem is formed between the two short complementary sequences, maximizing the quenching of the reporter by the quencher dye via FRET when the probe is free in solution. A fluorescent reporter dye signal is generated following the annealing of the probe to a complementary sequence on the template strand. The annealing of the molecular beacon to an intervening sequence between the two primers physically separates the reporter dye from the quencher dye and FRET is no longer possible. Unlike a Taqman® probe, however, molecular beacons do not depend on cleavage by the DNA polymerase to generate a signal. The probe is simply displaced during new strand synthesis. Displacement is facilitated by keeping the T_m differences between the probe and the two primers at a lower temperature, such as 5 °C instead of 10 °C for Taqman® probes. Overall,

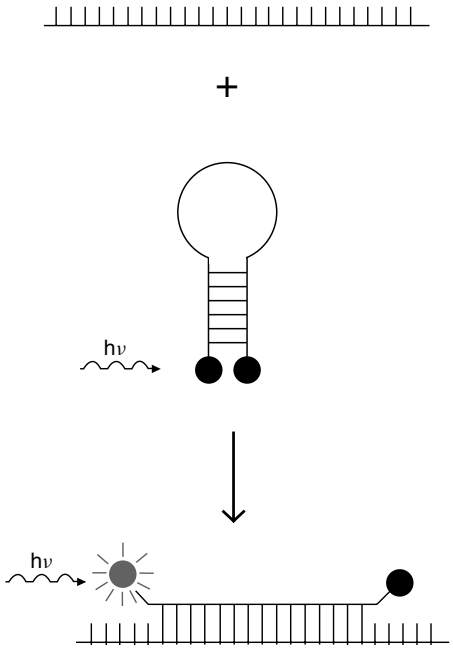

Fig. 7 Mechanism of signal generation for a molecular beacon probe. Designed complementary sequences at the 5′ and 3′ ends bring the reporter and quencher dyes in close proximity leading to much reduced reporter signal via FRET. Following template and beacon melting and annealing, full reporter signal is realized owing to loss of FRET. Unlike Taqman® probes, molecular beacons are not degraded and produce a signal only when annealed to the template.

when compared with Taqman® probes, molecular beacons have a higher signal to noise ratio due to optimal FRET between the reporter and quencher dyes. They have also been reported to work better on high G/C templates and show greater sensitivity to single-base mismatches, which makes them ideal for SNP (single nucleotide polymorphism) detection studies. However, they can be more challenging to design than Taqman® probes.

3. Hybridization probes are used primarily in conjunction with the Roche Lightcycler real-time detector, although they could be used on any real-time machine that can detect the reporter signal. For this assay system, two oligonucleotides, both with equal and higher T_m values than the primers, are made that again anneal to complementary sequences between the two PCR primers (Fig. 8). One is labeled with a donor dye on the 3′ end and the other has a signaling acceptor dye on the 5′ end. Unlike the Taqman® and molecular beacon probes that utilize FRET to quench the reporter signal, hybridization probes use the fluorescent signal induced by FRET as the reporter signal. The fluorescent signal is made when the two probes anneal to a complementary single-stranded DNA template. The excitation light stimulates the acceptor dye (green) and that emission energy is transferred to the acceptor dye (red) by FRET. The light emitted by the acceptor dye is monitored and recorded by the real-time

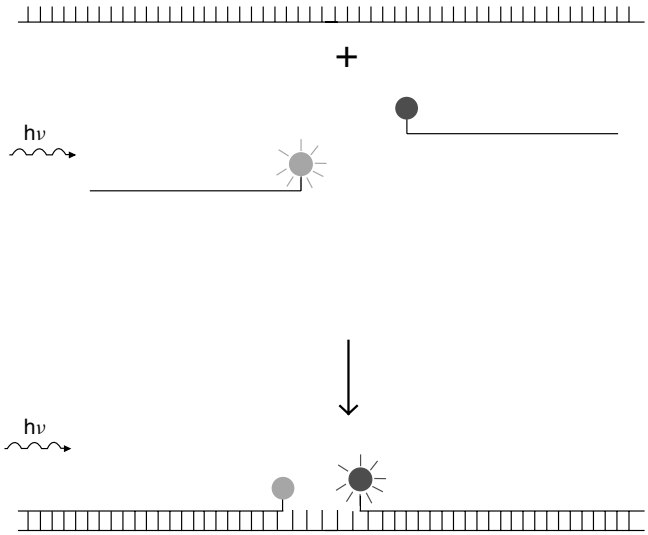

Fig. 8 Graphical representation showing the mechanism of action for a hybridization probe. Two oligo probes bearing a single dye each, one with a fluoroscein dye at the 3′ end and the other with a rhodamine dye at the 5′ end. When the two oligos anneal to a complementary template, the fluoroscein dye is excited by the light source in the instrument and transfers its energy to the rhodamine dye via FRET. FRET can only occur when the two dyes are in close proximity. The instrument is set to detect the rhodamine signal. The signal from the fluorescein dye is not monitored.

instrument as a positive signal. While free in solution, no signal is generated by the two probe molecules at the correct wavelength as the acceptor dye emission wavelength is not monitored and the reporter dye will not absorb the wavelength of the light source. As with molecular beacons, the probe molecules do not have to be cleaved. The advantage of this system is a low background. Similar to the two probe-based assays described above, this probe-based system is highly template specific. However, designing two tandem oligonucleotide probes that anneal between a pair of primers that will work with high efficiency can be even more challenging than the other two probe systems.

3 RNA and DNA Isolation for Real-time PCR

The key factor for isolating good DNA or RNA is how the sample is treated prior to nucleic acid isolation. If the sample is not treated properly and the macromolecules are degraded *in situ*, no amount of care during the nucleic acid isolation phase can rescue the sample. For animal, plant, or microbial sources, it is imperative that they are properly treated following harvest by either initiating isolation of nucleic acids immediately or processing the sample for storage that will preserve the RNA and/or DNA *in situ*. Quick-freezing of the sample in LN_2 followed by storage at $-80\,^{\circ}C$ works well to stabilize the nucleic acids in most samples. A relatively new option for sample storage from Ambion, RNALater, can be used to store samples for short times at room temperature or $-20\,^{\circ}C$ for extended periods of time.

Following sample collection, the next most important thing in the isolation process is to make sure the tissues or cells are disrupted rapidly in the isolation medium. For this purpose, a rotor-stator homogenizer or a bead-beater works very well for most samples.

3.1 Isolation of DNA

Procedures for the isolation of DNA from animal tissue or cells involve incubating the homogenate in buffers containing EDTA, SDS, and proteinase K at elevated temperatures ($50^{\circ}-60\,^{\circ}C$). This will destroy any remaining cellular structure and contaminating proteins while preserving the DNA. Ribonucleases A and T1 are added to degrade the RNA. The digest is then extracted with phenol, phenol-chloroform, and chloroform followed by ethanol precipitation of the DNA. Isolation of DNA from some eukaryotic microbes and most plants is more involved as they have carbohydrates that copurify with the DNA. For these samples, an extra purification step utilizing CTAB (cetyltrimethylammonium bromide) will free the DNA from the contaminants. It is not necessary to worry about shearing the DNA during isolation, as the amplified region for real-time PCR is quite small, in the range of 75 to 250 bases. A final purification over a silicon-based column will result in DNA of high purity suitable for PCR.

3.2 Isolation of RNA

The isolation of RNA can be more problematic than DNA primarily because RNA is much more susceptible to degradation prior to and during isolation. The primary

reason for measuring transcripts by quantitative real-time RT-PCR is to compare mRNA levels between control and experimental samples. To ensure transcript levels that reflect the original status of the source, it is important to stop any further changes in the RNA population as rapidly as possible after harvesting the sample. The best method for RNA isolation can depend on the origin of the sample. In general, a combination of thorough homogenization in a guanidinium/phenol-based buffer followed by purification on any of the commercially available silicon-based columns results in excellent yields and the highest quality RNA for real-time PCR. This approach will work for the vast majority of samples from microbes to mammalian tissue. As with DNA isolation, those sources that present problems for DNA isolation will present the same problems for RNA isolation. Methods are available in the literature for those particular tissues or organisms. One exception is isolating RNA from fixed and embedded tissue. We have found that a detergent-based isolation medium followed by proteinase K digestion of deparafinized tissue have proven to work best with limited amounts of starting material where extractions by organic solvents are not practical for maximal yields.

Two excellent sources describing multiple methods for the extraction of nucleic acids are ''Molecular Cloning'' and ''Current Protocols in Molecular Biology.''

4 Standards Used for Real-time Quantitative PCR

The term ''standard,'' when used in the context of real-time PCR, means any nucleic acid template that bears the amplicon sequence of the gene or transcript being interrogated. Standards are used to quantify the gene or transcript levels in unknown samples. This is usually accomplished by making a dilution series, 10-fold decrements are common, over a 5 to 6 log range of standard concentration. By assaying the dilution series of a standard along with samples of unknown target levels, it is possible to determine the level of the target sequence in the unknown samples relative to the standards.

The term ''absolute'' has been used in conjunction with real-time quantitative PCR. This is a misnomer as no set of universally used standard assays with independently measured and verified standards are currently available. The ideal situation would be a single, quantified standard from a central agency such as NIST (National Institute of Standards and Technology, USA) for every nucleic acid target used in a real-time PCR assay. However, it is currently not possible to measure the number of molecules in any standard preparation that will be functional in the PCR, other than by real-time PCR itself. In the absence of this ideal situation, the best that can be achieved is a measurement of target molecules in any sample relative to the nucleic acid standard being used. Standards currently in use are quantified on the basis of their total nucleic acid concentration using absorbance at A_{260} or fluorescent dye–binding assays such as picogreen, ribogreen, or oligreen from Molecular Probes/Invitrogen.

4.1 RNA Standards

Unquestionably, the best standard to use for quantitative real-time RT-PCR would be an RNA molecule bearing the target

region of the transcript being measured. This is because both the standard and the sample RNA target have to be converted into cDNA by reverse transcriptase as well as amplified by *Taq* DNA polymerase. Thus, the efficiency of both synthetic processes will be similar in both reactions for the RNA standard and RNA target sequences in the unknowns.

The simplest way to make an RNA standard is to dilute a concentrated, total RNA preparation. The problem with using total RNA to make a standard dilution curve is the highly variable amount of different transcripts in any RNA population. Thus, the number of dilution points detected will be variable for any given assay. Although it would be impractical to quantify unknown RNA samples using dilutions of a total RNA preparation, it does allow a measure of PCR efficiency (from the slope) and a determination of the relative low-end sensitivity of the assay.

The *in vitro* production of RNA of the size of an entire RNA molecule (some mRNAs are over 15 Kb in length) is not practical. However, it is possible to synthesize full-length RNA molecules *in vitro* that are <500 bases in length, in large quantities. To do so requires a double-stranded DNA template bearing the sequence that will be amplified during the PCR. The DNA template can then be cloned such that it is physically placed 3′ of a bacterial viral promoter sequence, usually T7 RNA polymerase. Alternatively, the T7 promoter can be added to the DNA target using a forward PCR primer with the promoter site added to the 5′ end of the primer. In either case, large quantities of RNA can be made per engineered DNA template. This is because RNA polymerases can use the same DNA template multiple times during a synthesis reaction. The full-length RNA is then separated and isolated from any shorter molecules in the total synthesis product utilizing an acrylamide gel. RNA standards are very stable over many years if stored at −80 °C and treated with care to avoid ribonuclease contamination. RNA standards can be quantified using an A_{260} measurement or, more specifically, by using the ribogreen fluorescent assay from Molecular Probes/Invitrogen.

The easiest RNA standard would be one that was synthesized *de novo* in the laboratory or by a company. The cost of RNA oligonucleotide synthesis has dropped dramatically in the last few years, mostly due to the increasing use of RNAi in research clinical applications. However, synthetic RNAs, the length of even the shortest assay amplicons (60–70 bases), are still very expensive compared to their DNA counterparts.

4.2 DNA Standards

From a practical point of view, DNA standards are much easier to use (no reverse transcriptase step required) and can be made in multiple ways inexpensively. The simplest DNA standard is the purified PCR product from one or more RT-PCR or PCR reactions. Once it has been determined that there is a single amplification product by polyacrylamide gel electrophoresis and excess primers and other reaction components have been removed, the PCR product can be quantified by A_{260} or using the picogreen fluorescent assay (Molecular Probes/Invitrogen). This method is easy, inexpensive, and a quick way to make a standard curve over a broad template concentration to test the efficiency and low-end sensitivity of a new real-time PCR assay.

Another approach to making a DNA standard is to clone an amplified double-stranded DNA product made from cDNA or a DNA template into a plasmid. Once a recombinant bacterial clone is established, a permanent resource for that DNA template is available. Making the DNA standard is as simple as a plasmid preparation and quantification of the purified DNA by A_{260} or picogreen assay.

As a standard for DNA samples, both of these methods are excellent. As standards for RT-PCR, however, both DNA standard types have two drawbacks: (1) DNA standards are not linked to the reverse transcription reaction and (2) cDNA is single stranded and DNA is double stranded, which means that when a single-stranded cDNA is being made into a double-stranded molecule during PCR cycle 1, a double-stranded standard is already being amplified. This must be kept in mind when using dsDNA standards to quantify RNA samples. A more detailed discussion of how standard curves are used to quantify samples is given in Sect. 6.2.

The easiest way to make a DNA standard that is also single stranded is to simply synthesize it yourself or have it made by a company on a DNA synthesizer. For this strategy to work, however, the assay amplicon has to be no longer than 100 bases, preferably less than 80. The ability of modern DNA synthesizers to make long oligonucleotides with high fidelity is quite good. However, there can be a subset of molecules in the oligonucleotide synthesis that are not completely deprotected (still have a blocking group attached), that have a

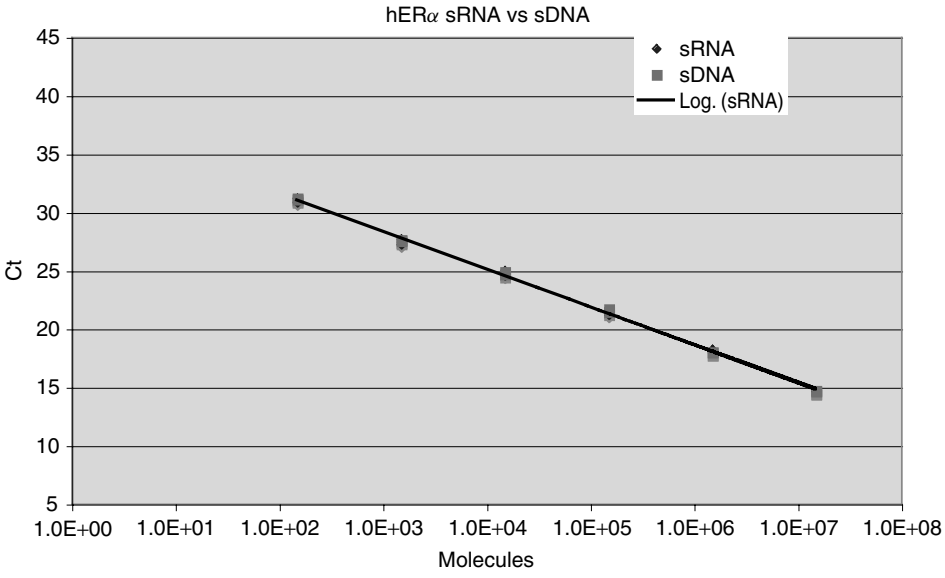

Fig. 9 A comparison made using an *in vitro* transcribed RNA standard to a synthetically manufactured oligo DNA standard for the human estrogen receptor α-(ERα) assay. Both standards were run on the same 96-well plate with identical two-step chemistry. RNA and DNA standards can work identically under the same assay conditions.

missing or inappropriate base in one or more positions and thus cannot serve as a fully functional template in the polymerase chain reaction. Yields of full-length molecules, following isolation on a polyacrylamide gel, are such that one synthesis will easily last the lifetime of the investigator running the assay.

The real question is, do DNA oligo standards yield equivalent results compared to RNA standards? Our experience has been that they do make comparable standards. One example is the comparison of standard curves generated from a single-stranded DNA oligonucleotide versus an *in vitro* transcribed RNA for the human estrogen receptor α-transcript (Fig. 9). The slopes and values for the two standards are nearly identical, showing that the RNA has been converted to cDNA and both templates amplified equally over a 6-log range of template concentrations. One caveat is that assays with amplicons over 100 bases have been difficult to test in the same way because of problems in synthesizing longer oligonucleotides. Nonetheless, in multiple assays, single-stranded DNA oligonucleotides under 100 bases have been shown to work just as well as their RNA counterparts. This means that for the relatively short amplicons used in real-time PCR assays, the RT efficiency has to be near 100% when assay-specific primers are used.

5
Real-time PCR Assay Design

The hallmarks of real-time PCR are the specificity, sensitivity, and efficiency of the assays. An assay is specific if it can be demonstrated that the detected target sequence is the only one being measured in the real-time PCR. Sensitivity is the lowest detectable amount of template that still maintains a linear relationship in a dilution series of standard template. A detectable signal for an assay that no longer falls on the standard curve is not usable for quantification and is below the sensitivity of the assay. The efficiency of an assay is 100% when every molecule in the reaction is exactly doubled. The primary factor that determines if an assay will have high levels of these three characteristics is determined by how well it is designed.

5.1
Available Software

Many multifaceted molecular biology software programs available today, such as MacVector, Vector NTI, Oligo, and others, have subroutines for designing compatible primer pairs for primer-based real-time PCR. Designing assays with an intervening oligonucleotide probe, however, requires a different software algorithm. In all software programs, primers are selected on the basis of criteria set by the investigator, the target specified, and with the goal that the oligonucleotide components not interact with one another during the PCR. Such interactions can lead to the formation of primer dimers during the PCR that increase the baseline fluorescent signal, called *noise*, of the assay. When designing a probe-based assay, the intervening probe sequence has to be taken into account as well. Only a few programs on the market are designed to find primer pairs and a compatible probe together as an assay set.

Table 2 lists the most prevalently used of the available commercial software and those that can be accessed and used over the Web.

5.2 Basic Rules for Real-time Assay Development

Guidelines for designing primer- or probe-based assays are outlined in Table 3. By following these guidelines, we have designed assays that have worked well experimentally for many hundreds of transcripts, including viral, prokaryotic, and eukaryotic gene sequences. What has been proven empirically is that the efficiency of an assay is determined solely by how well the primers work as a pair. The probe, if present, is a signaling molecule and adds greatly to assay specificity.

SYBR Green I dye-based and simple fluorescent-labeled primer assays follow the same rules of assay design as for non-fluorescent PCR reactions. Primer concentrations should be kept relatively low, 50 to 100 nM, to discourage nonspecific priming. In contrast, when using probe-based assays and Taqman® assays, in particular, higher primer concentrations are required for optimal performance, 300 to 400 nM.

It is best to keep the T_m (melting temperature) of both primers the same. This simplifies assay quality control (QC) as changes in annealing temperature will affect the annealing of both primers equally. One way to avoid nonspecific binding is by raising the annealing temperature slightly during the PCR. Conversely, when little to no PCR product is formed, lowering the temperature may lead to increased primer binding to the template. Keeping the percent G/C content similar for both primers has also been found to be best for optimal assay performance. Pairing a short primer with a high G/C content and a long primer with low G/C content will not result in as efficient an assay as when the %G/C content is more balanced. Primers work best if they have 2 to 3 G- or C-residues in the last five bases of the primer sequence at the 3′ end. The binding specificity of PCR primers resides in the last 5 to 6 bases at their 3′ end; the rest of the primer sequence determines the annealing temperature. Many investigators insist on putting a G or C residue on

Tab. 3 Rules for the design of real-time PCR assays.

Rules for primer design		
Topic	*Rule*	*Comment*
Primer concentrations	Set primer concentrations to 50–100 nM for SYBR green and simple fluorescent primer–based assays; 300–400 nM for Taqman probe–based assays	For SYBR green assays, a low primer concentration will discourage primer dimers and false priming; fluorescently labeled primers may require higher concentrations depending on signal strength
Primer T_m	The primer T_m values should be equal	Good for assay optimization; raising or lowering the annealing temperature will have an equal effect on both primers
Primer % G/C	%G/C of a primer pair should be within 25% of one another	Primers with very disparate %G/C values work satisfactorily but keeping the %G/C close, and thus primer lengths, works best empirically
Primer structure	Primers work best with 2–3 G/Cs in the last 5 bases	Too many Gs or Cs in the last 5 bases will cause false priming and low efficiencies; too few will not prime well
3′ Clamp	G/C clamp on 3′ end works well but is not necessary	Primers with 3′ G- or C-residues work well but primers that end in an A or T can work equally well; 2 or more 3′-Ts do not work well
G residues	No more than 3 Gs in a row for primers or probes; causes a bend in the oligo structure	Multiple G-residues cause the DNA structure to bend which is not conducive to good binding for a short oligo, not such an issue for a long DNA or RNA template
Amplicon T_m	Increase T_m of the amplicon from 85 to 95 °C for high G/C regions or organisms	Often, software will set the optimal amplicon T_m at 85 °C but higher G/C sequences will require a higher setting
Rules for probe design		
Topic	*Rule*	*Comment*
5′-G residue	Reporter dye should not be linked to a G-residue	Guanine will act as a FRET pair with many fluorescein dyes and quench the signal (e.g. FAM, TET, VIC, etc.)
Probe T_m	Probes should have an 8–10 °C higher T_m than the primers	Probe T_m should be 8–10 °C above the primer T_m to ensure they can bind before the primers and generate a signal by probe cleavage or unfolding
Probe length	Taqman probes should not be over 30 bases or will not quench properly	Empirical experiments have shown that cleavage probes over 30 bases in length do not quench well and thus give a poor signal to noise ratio. High A/T rich sequences lead to long probes, lowering the T_m to 55 or 50 °C allows reasonable probe length with standard reagents, assay will still work at 55° or 60 °C
More Cs than Gs	Probes should have more Cs than Gs, particularly if there is a large imbalance between the two	Multiple G-residues cause the DNA structure to bend which is not conducive to binding in a short oligonucleotide probes that have many more G- than C-residues should be made from the complementary sequence

the 3′ end of the primer. This is called ''clamping'' the primer. Although primers work well when ''clamped,'' it is not an absolute requirement for maximal PCR efficiency. Long homogeneous runs of any base should be avoided, but, in particular, G-residues. Tandem runs of G-residues over three bases in length tend to cause a bend in the oligonucleotide structure and this deviation from linear structure will impair the ability of the primer (or probe) to anneal properly.

There are rules for the design of fluorescently labeled probes as well. Probes labeled on the 5′ end with a fluorescein dye (e.g. 6-FAM, TET, VIC, etc.) should not begin with a G-residue. Guanine has the ability to effectively diminish the fluorescein signal, as mentioned previously for LUX primers. It is important that probes have a 5 to 10 °C higher T_m than the primers to ensure they bind to the template prior to the primers. This is particularly important for Taqman® probes that require cleavage of the probe for signal production. Similarly, Taqman® probes should be no longer than 30 bases. Probes longer than 30 bases will not quench well prior to cleavage because of poor FRET between the reporter and quencher dyes and generate little increase in fluorescent signal following cleavage compared to shorter, more efficiently quenched probes. When making assays for organisms with a low G/C content (lower than 40%), keeping the probe shorter than 30 bases can be problematic. An easy solution to this problem is simply to lower the optimal T_m setting during assay design. Taqman® assays work very well utilizing 50° or 55 °C annealing temperatures instead of the more common 60 °C. Probe length is not an issue for molecular beacons because of the forced close proximity of the reporter and quencher dyes in the probe design, or dual probe assays designed for the Lightcycler, where again the fluorescent signal comes from the close proximity of the dyes following binding. In general, probes work better if they have more C- than G-residues, particularly if there is a large imbalance between the two bases. This is a general rule applicable to all oligonucleotides used in real-time PCR.

5.3 Key Factors in Assay Development

The most important part of assay design is selecting the correct sequence before you begin. It is critical to have confidence in the accuracy and specificity of the sequence being investigated. There are two key issues, first to know that the sequence in question is accurate and second that the assay will be specific for the intended target. Mismatches between the actual sequence and those in the primers or probe can have a negative effect on assay performance. Genes or transcripts with regions of highly conserved sequence among family members can be problematic. Splice variants, and pseudogenes are some of the main issues to keep in mind when selecting a particular region within the sequence for assay design. For sequenced genomes with information available in public databases, accuracy usually can be determined *in silico*. However, for other organisms, it is important that the target sequence be validated prior to assay design. In this case, it may be necessary to sequence the final PCR product during assay development to ensure the intended target is being amplified.

When possible, it can be very useful to download sequences from other species for the same transcript or gene. When a human assay is the goal, for example, retrieving the human, mouse, and rat

or other mammalian sequences can yield helpful and sometimes unexpected information. An alignment of all species will sometimes illuminate conserved regions that may be useful in making a multispecies assay or point out a region to be avoided if a transgenic mouse with a human gene is the target. Multiple species alignments also may point out splice variants present in the rat or mouse sequence in this example, not known in the human transcript. In these instances, avoid exons involved in any known splice variants. It may be the same splice variant that exists in the human as well, but has not yet been observed and/or reported.

Another issue is making a transcript-specific assay for one family member of a multigene family when all members share a large amount of sequence homology. Again, alignments will allow you to find unique places to place an assay. As mentioned above, making mouse- and human-specific assays for the same transcript in a transgenic environment can be a challenge. In this case, it is critical there be no cross-detection of the transcripts from the two species. Should the sequence homology be highly conserved throughout the coding region, an assay can be placed in the 5′ or 3′ untranslated region (UTR). However, these regions of the transcript can contain a sequence that is not well balanced among the four bases and, thus, not very PCR friendly.

There are some philosophical issues to be decided prior to designing a real-time PCR assay. The first is whether to design assays across intron/exon junction regions of a transcript. The primary reason for spanning a junction region is to avoid the detection of contaminating DNA in the RNA preparation. The sequence surrounding junctions is not always compatible with efficient real-time PCR assay design. This is not a problem for primer-based assay with larger amplicons (i.e., 250 bases), but can be a problem for probe-based assays with shorter amplicons (i.e., 65–80 bases). Regardless of assay type, one thing to keep in mind is that there are a lot of pseudogenes in the mammalian genome. Pseudogenes are spliced versions of transcripts that have been introduced back into the DNA sequence, most likely by retroviruses. One estimate is the human genome contains 30 000 genes and 20 000 pseudogenes. Some genes have multiple pseudogenes and others have none. The problem is that it is impossible to predict which have them and which do not. Therefore, crossing a junction does not guarantee you will not detect contaminating DNA in your RNA sample. However, in practice, it does reduce background from DNA contamination for many transcripts. Philosophically, it is more important to have an efficient assay than to insist on crossing a junction. However, for assays that do not cross an intron/exon junction, this means that all the RNA samples have to be DNase I treated to ensure that any contaminating DNA does not contribute a significant signal. DNase I treatment is very straightforward, has little deleterious effect on the RNA, and takes only a short time. Three key factors to keep in mind when DNase I treating RNA samples: (1) keep the DNase I concentration low, a 1/10 dilution of the stock enzyme using a volume of diluted enzyme dependent on the RNA concentration; (2) DNase I is a divalent cation-requiring enzyme, 1-mM $MgCl_2$ is sufficient for the reaction; and (3) divalent cations and high heat will degrade RNA, keep the DNase I heat killing temperature and time low and brief; 75 °C and 10 min are sufficient.

Before an assay is put to use, it is important that it be tested for three important criteria: specificity, efficiency, and sensitivity. We call the empirical determination of these three assay characteristics, quality control (QC). Quality control procedures are slightly different for SYBR Green I and primer-based assays, compared to probe-based and scorpion primer assays. Determining assay specificity for primer-based assays involves running the first real-time PCR products on a DNA acrylamide gel to look closely for extra-assay bands and primer dimers. As mentioned earlier, primer dimers will increase the fluorescent background of the assay and reduce the signal to noise ratio. The latter can have a deleterious effect on assay sensitivity. A melt-curve should be run at the end of these assays, as well, to make sure the product produced makes a single, sharp melt peak. This is also true for every run done with primer-based assays. However, a word of caution with regard to the DNA profiles generated during melt-curve analysis. This method is a quick analysis of the homogeneity of the PCR products generated in every well on the plate. However, it is not a very sensitive assay. PCR products that are not that far apart in size will merely make the melt peak slightly wider, you will not get two distinct peaks unless the bands are quite disparate in size. For this assay type, the amplicon should be 200 to 250 bases in length so that primer dimers, less than 30 mers, can be readily seen as a separately resolved band on the resulting graph. The determination of assay sensitivity and efficiency is the same as for probe-based assays and will be discussed in the following text.

Probe-based assays and scorpion primers have a higher level of template specificity. For this reason, all QC analyses can be done on the real-time machine without the need for an acrylamide gel. The reason is that extra bands or primer dimers, should they be made, will not be detected because the intervening probe oligonucleotide(s) or the tail of the scorpion primer will bind solely to the central region of the correct amplicon and that binding is essential for the generation of a fluorescent signal. Therefore, for these assay types, all components must work in concert to obtain a fluorescent signal. Further, unlike SYBR Green I or fluorescent primer–based assays, the shortest amplicon possible for probe-based assays is the most desirable. The shorter the amplicon, the easier it is to achieve maximal efficiency of the PCR.

Once assay specificity has been established, the overriding theme that should be observed during assay QC is the maximization of assay efficiency and sensitivity. A proven strategy for achieving this goal utilized in designing hundreds of Taqman® probe–based assays is to order multiple primers (two forward and two reverse) around a single probe. This same design principle of multiple primers should be utilized for primer-based assays as well to minimize possible extra-assay bands and primer dimers. Testing the primers in all possible combinations will empirically determine the best primer pair for that assay. The current design software is not sophisticated enough, at present, to ensure an ideal assay every time. The primer pair that results in the lowest number of cycles necessary for a detectable signal and the highest probe dequench at a fixed template concentration is the best primer pair. In some cases, the four primer combinations may not differ greatly, but one pair will fit the optimal criteria better than the other three. In other cases, a larger 3 by 4 primer matrix (12 unique combinations) resulted

in only two acceptable primer combinations and only one of those resulted in an optimal assay. There are other examples where moving a primer one base up or down the sequence had a dramatic effect on assay performance. In all of these examples, all the primers fit the design rules outlined previously. In our experience, only by empirical experimentation can the best primer pair for an assay be determined.

Once an optimal primer pair with high template specificity has been selected, the sensitivity and efficiency of the assay must be empirically determined. Both can be found from running a dilution series of an assay standard. A standard curve should be run during assay QC, even if one is not going to be used with unknown samples, to determine assay efficiency and sensitivity. From the slope of the assay standard dilution series, assay efficiency can be determined. Acceptable slopes are -3.2 to -3.5 (see Table 7). In the real world, assays having this range of slopes are seen often and will yield excellent results. The lowest point on the standard curve that is no longer linear with the higher dilutions (falls off the standard curve) is no longer quantifiable in that assay. This is just past the low-end sensitivity for the assay. It is critical that this point be determined during assay QC so that incorrect values are not reported for the assay. This is particularly important for assays that will not include a standard dilution series on every plate.

Multiplexing is having the components for more than one assay in a single reaction. What are the design criteria for a good multiplexed assay? An acceptable multiplexed set of assays should have the same efficiency and sensitivity for their respective target sequences together that they have when run in isolation. This can only be achieved when the primers or primers and probe from one assay are able to amplify their target sequence without interfering with the other assay components in the reaction and visa versa. This means that two assays that work perfectly in isolation may very well not work with the same efficiency when combined. Thus, multiplexed assays have to be designed together as a super set to ensure operational autonomy. However, currently, there is no software available to the end user to assist in this process. Thus, beyond checking for pair-wise interactions among the reactants using available software, the optimization of a multiplex assay is an empirical one.

6 Running a Real-time PCR Experiment

It would not be practical in this review to discuss every nuance of performing a real-time PCR experiment. However, there are some important points that should be taken into consideration before any experiment is initiated.

6.1 Practical Considerations

When working with RNA, standard laboratory procedures should be followed: gloves, virgin plasticware whenever possible (RNase-free), and use of reagents and enzymes that are RNase-free. The most important component is the water. It is worth the expense to purchase commercially available nuclease-free water. DEPC-treated water made in the laboratory is not good for real-time PCR use because residual DEPC (diethyl pyrocarbonate) is a PCR inhibitor. This residue is not present in commercially available nuclease-free water.

Any lab that practices PCR will experience contamination problems, primarily from amplification products from earlier amplification reactions. Problems can be minimized by following a few, easy precautions. First, what is amplified in the tubes or plate wells should stay in the tubes or plate wells. If you have to use PCR products for a gel, for example, open the tube or plate and run the gel in a different room than the one you use to set up your RT and/or PCR reactions. Secondly, use a different set of pipettes in that room. It is best to make small aliquots of water in disposable labware for daily use and dispose of these at the end of the day. Use a different aliquot of water in each room. In time, everything that is exposed to concentrated DNA template for an assay will become contaminated by DNA-containing aerosols that are generated during pipetting. For amplicons of 70 to 250 bases, real-time PCR has the sensitivity to accurately detect template molecules in the high attogram (10^{-18} grams) range. Wipe the barrels of your pipetters down with 70% ethanol regularly to help eliminate this problem.

In an attempt to circumvent the contamination problem, many commercial kits substitute dUTP for dTTP and come with the enzyme uracil N-glycosylase (from the *Escherichia coli ung* gene). This enzyme will remove dU from any DNA molecule that contains it, degrading the template. Use of dUTP and uracil *N*-glycosylase prior to beginning the PCR is advertised by many companies as a way of eliminating potential contamination by amplified DNA. There are two problems with this approach. First, dUTP has to be used at twice the concentration of dTTP because it is not incorporated as efficiently by *Taq*. Secondly, other potentially contaminating templates in the laboratory (e.g. cDNAs made without dU, DNA standards and genomic DNA) will not contain dU and those will cause contamination anyway. In the end, using this strategy costs a lot more, increases the time of every instrument run, and adds nothing to the amplification of the final PCR product.

In practice, amplification of a target starting from an RNA substrate is more difficult than from DNA. Most failed RT-PCRs are due to a failed RT reaction. There are several reasons why the reverse transcriptase step does not succeed: (1) a very low abundance of the target transcript; (2) nonspecific binding of the primers and thus inefficient production of the correct cDNA template; (3) the inability to make enough complete templates of a long cDNA for the ensuing PCR; (4) a badly degraded RNA template or; (5) the presence of reverse transcriptase inhibitors in the RNA preparation. In contrast, the PCR is a comparatively robust reaction primarily because the DNA template is already present. Most failed PCRs stem from a bad component such as degraded dNTPs, improper or degraded primers, not enough $MgCl_2$, PCR inhibitors in the sample, and most often degraded or incorrect template.

6.2 Reagents

Most manufacturers make two kinds of reagent kits for real-time RT-PCR, a one-step and a two-step kit. In a two-step procedure, cDNA is made in one tube under ideal reaction conditions utilizing a thermocycler or water bath at the optimal temperature followed by the use of some or all of that cDNA for the succeeding PCR, also done under ideal reaction conditions, in a thermocycler or a real-time PCR machine. In a one-step protocol, RNA

template is added to a combined reagent mix containing both reverse transcriptase and a hot-start *Taq*. The RT and PCR reactions are performed sequentially in a real-time instrument. Hot-start *Taq* has made one-step protocols possible as the RT reaction is run at a lower temperature than that required for activation of the hot-start *Taq*. This method saves time and requires fewer manipulations. However, it has been shown empirically that one-step procedures are not as sensitive to low RNA template concentrations as two-step protocols. This is most likely because the components of the reaction mixture are a compromise to accommodate both enzymatic reactions. In those instances where transcript levels could be quite low and/or highly variable from assay to assay, use of a two-step protocol gives the best template sensitivity. However, if the same assays are being run repeatedly utilizing similar samples that have a known template range, a time-saving one-step procedure is more efficient.

Purchasing assay reagents from a company saves the time required to put the individual reagents together and provides a consistent reagent base for laboratory operations. When an investigator is new to real-time PCR, it is best to purchase a reagent kit to eliminate that variable should other problems arise. However, there is a financial cost to be paid for this convenience. Over time, the cost savings of constructing your own reagent mixes can be substantial. Further, knowing exactly what components are in each reaction mixture and their laboratory history makes tracking down reagent problems much easier.

The most important concept in making your own assay buffers is that of the master mix. A master mix is a large volume of all the reaction components common to each reaction, that is, for PCR that would be everything but the template, for a single assay. This will ensure that every reaction is as close to the same as possible, except for the one variable being measured.

An example of a master mix for a reverse transcriptase reaction using an assay-specific reverse primer and the reaction conditions are shown in Table 4. The RT master mix is for a single assay and is designed to easily continue on to the following real-time PCR. For wells where a no amplification control (no reverse transcriptase) reaction is required, some of this master mix can be added to a second tube just prior to the addition of the reverse transcriptase.

For SYBR Green I, or a fluorescent primer–based assay, it is important to use a hot-start *Taq* to minimize the number of nonspecific bands and primer dimers formed. An example of a master mix for the PCR we have used successively utilizing SYBR Green I can be seen in Table 5. For best results, we have found that a three-step PCR cycle will eliminate most primer dimmers during data collection at 72 °C.

[e] Hot-start *Taq* required.

This buffer and cycling protocol would most likely work well for fluorescently labeled primers as well. For probe-based assays, a simpler PCR master mix is shown in Table 6. Note that with probe-based assays, a faster two-step PCR cycle can be used. In both cases, the master mix is designed to be added directly to the 10-µL post-RT cDNA reaction and inserted directly into a real-time PCR instrument for analysis.

6.3 Controls

One thing that is often not stressed enough is the importance of running the proper controls in a real-time PCR experiment. There are two essential controls to be considered when running a real-time PCR experiment. The first is a no-template control, sometimes called the ''NTC''. It is critical to know if there is low-level contamination present in the reaction mixture, especially if the ddCt method is being used (Sect. 7.4). One might argue that using commercial master mixes would make this control superfluous. However, the most likely source of contamination comes from the reagents added by the investigator. A second important control is for the reverse transcriptase reaction to check for signal from DNA contamination. This is done by running a reaction without reverse transcriptase, also known as a ''no amplification control'' or ''NAC.'' As stated above, designing assays across intron/exon junctions is no guarantee that there will be no signal from DNA contamination. Running this control on junction-spanning assays once during QC using 20 to 50 ng of genomic DNA, much higher than any

Tab. 6 Example probe-based PCR reaction mix.

contamination level, will determine the sensitivity of the assay to extraneous DNA. For assays that do not cross a junction, we run one NAC for every sample on each 96-well assay plate. Even though each sample has been treated with DNase I, some assays are much more sensitive to DNA contamination than others, and uniform elimination of DNA contamination is not guaranteed. This control is particularly important for low-level transcripts where it will take 25 to 30 cycles for template detection. Control information for each assay should be included in all manuscripts that report data from real-time PCR experiments.

7 Data Analysis

In reality, it is nearly impossible for the person analyzing real-time PCR data to change the relationship of the samples with one another. That is because of the way the fluorescent signals are detected and the data recorded in the software. Having said that, data analysis can be performed incorrectly and have an impact on the final values obtained for the samples.

As with all quantitative techniques, it is important to compensate for differences in nucleic acid concentration from sample to sample. This process is called *sample normalization*. The most common method of normalizing sample values is to divide those values by values from an invariant transcript or gene, depending on whether the samples are RNA or DNA. If both the assay of interest and the one used to normalize the data have been incorrectly analyzed, the resulting ratio can be far from the true value, which can lead to an incorrect interpretation of the final data. Assay normalization will be discussed in Sect. 7.2.

7.1 Baseline Boundaries and Threshold Levels

The two most important settings for data analysis are the range of cycles that will define the baseline and the threshold. The baseline range represents a number of early cycles where only background signal can be detected. Thus, the signal is steady within this set of cycles. The rule of thumb for setting the upper end of this range is two cycles below the cycle where the highest signal on the plate or in a set of tubes is detected. Some software programs calculate the values for each individual sample on the basis of the baseline setting of the whole sample set. Others base their calculations on each individual well or tube. The low-end setting of the background defaults to cycle 3 in most software programs. This is because the first two cycles can have slightly higher overall signals as the PCR begins. This phenomenon is strictly related to the quenching efficiency of the fluorescent signaling mechanism for all, but SYBR Green I assays.

The cycle threshold (Ct) or crossing point (Cp) is the number of cycles it takes the fluorescent signal intensity from the sample to reach an arbitrary set value. In practical terms, the threshold or crossing point is represented by a horizontal line set across the rising amplification curves. The threshold setting is at a fluorescence intensity level significantly above the background signal. The minimum threshold is usually set at 10 times the standard deviation of the mean of the fluorescent signal(s) within the background range. The threshold is either preset in the software to a fixed value or determined by an algorithm in the software. In either case, it can be changed by the investigator. However, it is important that the threshold stay within the geometric part of the amplification curves of all samples being analyzed. The Ct or Cp is calculated from the fluorescence intensity values measured by the real-time instrument for all the samples in the experiment. Figure 10 shows a magnified view of the low end of the fluorescence scale from a real-time experiment to emphasize the baseline and threshold settings in relation to the amplification curves over a 6-log standard dilution series. In this case, the baseline is set from 3 to10 as the highest signal on the plate has a Ct of just over 12 cycles. The threshold is set at a fluorescent intensity (deltaRn) of 0.1, which is well within the geometric phase of this assay. This data was collected on an ABI 7700. Different software will have different relative scales for the *y*-axis. Thus, these absolute values will not be applicable to all real-time machines. However, the principles of how to set the baseline and threshold will be the same for all real-time PCR instruments.

7.2 Fluorescent Signal and Sample Normalization

The fluorescent signal values from a real-time PCR run can be reported in up to three different ways. The first is the raw fluorescence, which will have a scale commensurate with the sensitivity of the detector in the machine and the readout of the software. This is a measure of the raw signal coming from each well or tube and is often labeled R. The second value is called the deltaR (ΔR), which is calculated by subtracting the background signal in the well or tube from the raw fluorescence R and equals the net positive signal in the well or tube. This normalizes the signal for each individual

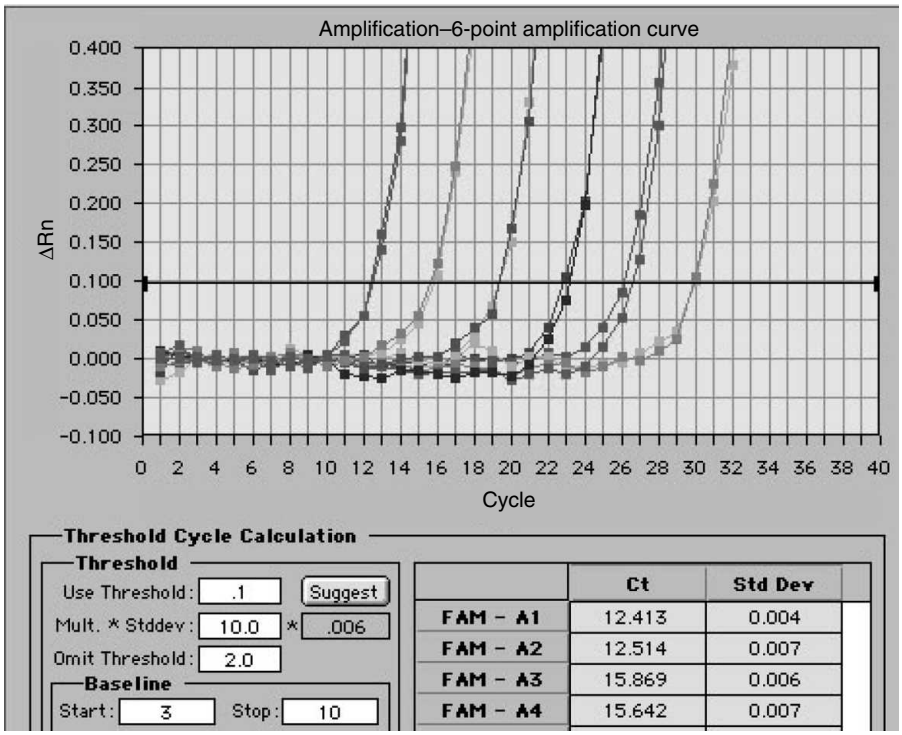

Fig. 10 Magnified view of the fluorescent signal in the baseline phase in relation to the threshold setting. A demonstration of setting the threshold high enough to be above the fluorescent signals (noise) in the baseline, but low enough to be within the geometric phase for each amplification curve. The threshold is the black horizontal line at 0.1 ΔRn (see color plate p. xxxvi).

well or tube for background differences. In machines that use ROX as an internal reference dye within the master mix, the intensity can be reported in a third way, as the deltaRn (ΔRn), which equals the ΔR/ROX signal. The ROX signal detected by the real-time instrument in each well or tube should be equivalent in theory, but not always in practice. This signal will vary with the mechanical light path and sensitivity of the instrument. By dividing by the ROX signal, the net fluorescence from each sample is normalized for any differences in signal intensity from well to well. The deltaRn calculation is the first normalization process in data analysis.

As mentioned earlier, the way to level the playing field for all samples in an experiment is to divide the primary data by some value that is a measure of some invariant component within the sample. The ratio between the invariant gene or transcript and the gene or transcript of interest corrects for differences in the amount of DNA or RNA added into the assay. For DNA experiments, the genes selected for normalization are usually present in a single copy per genome such as ApoB100 for mammalian samples. For transcript normalization, however, this can be more problematic. The critical criterion for using a transcript for data normalization is that it be at the same level

in all the samples (e.g. transcripts/cell), regardless of the experimental procedure. For many experiments, transcripts such as β-actin remain constant over the course of an experiment. However, in some experiments, the treatment protocol for the experimental samples, such as the addition of drugs or changes in the physical conditions compared to controls, can cause a change in the relative level of housekeeping genes. In this case, housekeeping genes have been observed to change in tandem with the transcripts of interest. Dividing sample values by those from housekeeping genes that mirror the changes seen in the target transcripts will result in a ratio showing no change with treatment. It is critical, therefore, to make sure the transcript being used is biologically invariant throughout the experiment for all samples.

The question of what transcript to use for data normalization is one with no stock answer. Every experiment has to be monitored for changes in the transcript chosen to normalize the data. A paper looking at different concentrations of housekeeping genes commonly used to normalize real-time PCR data from many tissue types found that the amount of each housekeeping transcript was variable from tissue to tissue and that no single transcript was optimal for all tissues investigated. They concluded that all transcripts can change slightly with treatment so the best way to combat this effect was to use a minimum of three housekeeping genes for data normalization. Although this was a very a good study, the economics and time constraints of this approach have kept it from being widely adopted.

A way to skirt the problem is to use 18SrRNA or 28SrRNA. These are the two most abundant RNA species in any eukaryotic cell and are usually stable to most experimental perturbations. Some would argue that using RNA polymerase III transcripts (ribosomal RNA) to normalize RNA polymerase II transcripts (messenger RNA) is not appropriate because they are at much different levels in the cell and under different regulatory pressures within the cell. For most experimental protocols, however, the two ribosomal RNAs work well for data normalization. However, in certain experiments, it has been shown that even the ribosomal transcripts can be affected by the experimental conditions.

There are other instances where any transcript would not be appropriate for data normalization. They include studies involving apoptosis, measuring DNA or RNA in the serum, actinomycin D studies of mRNA half-life, and instances where the experimental sample has more cell types than the control, for example, sites of inflammation. In these cases, the best alternative is to measure total RNA or DNA using a fluorescent assay such as the ribogreen or picogreen assays respectively from Molecular Probes. Measuring the total nucleic acid present in a sample in this manner is far superior to estimating their concentration using absorbance at 260 nM because absorbance will detect free nucleotides, very short oligonucleotides, contaminating DNA or RNA, and impurities that absorb light at this wavelength. None of these would be detected in a real-time PCR assay, but would have an inconsistent effect on the value for each sample and, thus, on their final normalized values.

7.3 Quantification Using a Standard Curve

There are experiments where it is not necessary to quantify the results. In these

cases, a determination of the presence or absence of the target sequence is sufficient. Examples are the presence or absence of a translocation in a tumor population or a pathogen in a tissue. However, the majority of studies require an accurate measure of the number of target molecules detected.

One method for accomplishing this goal is to run a dilution series of a quantified assay template alongside the unknown samples. The kinds of standards that can be used for this purpose were discussed in Sect. 4. In practice, a 10-fold dilution series spanning a 5-log concentration range of standard template is commonly used for quantification of unknown samples. However, during QC, a 6- to 7-log curve is used to determine the efficiency and lowest endpoint (sensitivity) of the assay. An example of a 6-log standard curve is shown in Fig. 11. In this example, the lowest dilution falls on the linear line and thus defines the low end of this assay, 200 molecules, because the last dilution, 7 logs, did not fall on the standard curve (not shown). The lowest detectable level for any assay, and thus its sensitivity, is the last dilution that is still on the standard curve. Unknown samples with Ct values below this level cannot be accurately quantified by the assay. It is extremely important to determine the low-end value for each assay in use. Otherwise, values may be reported that are not within the linear range of the assay and will not represent the true measure of the target. This is because the software is written with the assumption that the Ct or Cp value for the sample falls on the standard curve. If this assumption is not true and the Ct is off the curve, the value assigned to that sample by the software will be incorrect because the Ct value will be forced to fit the curve and an overestimate will result.

The standard curve has a negative slope because the more molecules there are, the fewer PCR cycles it takes for the signal in the reaction to reach the threshold (Ct). In Fig. 11, there are three values associated with the quality of the standard curve, which is a refection of the quality of the assay. The first is the slope from which you can calculate the PCR efficiency of the reaction. The slope (rise over run) is a measure of how many PCR cycles it takes to amplify the template 10-fold. The efficiency is derived from the amplification calculation. The relationship of assay slope to PCR efficiency and template amplification per cycle can be seen in Table 7. From Table 7, a slope of −3.33 equals 100% efficiency and an ideal amplification of template per cycle of 1 to 2. Therefore, the difference between each point in the standard curve is 3.33 cycles (y-axis) for every 10-fold dilution of standard template (Fig. 11). The second value is the y-intercept, which is the theoretical number of cycles required to generate a measurable signal (Ct) from a single template molecule. It is theoretical because most real-time quantitative PCR assays are not sensitive enough to maintain linearity down to one molecule. For RT-PCR, linearity to the low hundreds of molecules is very good due to the inhibition of *Taq* DNA polymerase by reverse transcriptase. The practical utility of this number is it tells you when your standard has been calibrated properly. Values from 36 to 38 cycles are acceptable due to variations in the slope from assay to assay. The third number is r^2 or correlation coefficient, which tells you how well the values making up the standard curve fall on a straight line. For real-time PCR, this value should not be below 0.990 for a good assay and is generally higher than 0.995.

Tab. 7 PCR efficiency versus assay slope.

Assay slope	*PCR efficiency*	*Product amplification*
−3.60	89.6%	1.90
−3.55	91.3%	1.91
−0.60	93.1%	1.93
−3.45	94.9%	1.95
−3.40	96.8%	1.97
−3.35	98.8%	1.99
−3.33	100.0%	2.00
−3.30	101.0%	2.01
−0.12	103.1%	2.03
−3.20	105.4%	2.05
−3.15	107.7%	2.08
−3.10	110.2%	2.10

Exponential amplification = 10E(−1/slope).
Efficiency = [10E(−1/slope)]−1.

Molecule numbers are determined for each unknown sample by interpolation from the standard curve. Each unknown is measured in duplicate or triplicate and the mean of the measurements made by the real-time instrument, the Ct values, are averaged in software. Using the mean Ct, the numbers of molecules are determined for each unknown. Following the red lines in the example seen in Fig. 11, a Ct of 29.5 would equate to 200 molecules of target sequence in the sample, relative to this standard preparation. The software determines a formula for the standard curve using a perturbation of $y = mx + b$, where $m =$ slope and b is the y-intercept. The investigator defines how many molecules are assigned to each dilution of standard on the basis of the best measurement possible. The number of molecules, relative to the standard being used, can be calculated for a defined mass using the length of the standard and taking into account whether it is single or double-stranded. The software then uses the formula for the standard curve to calculate the number of molecules for every unknown sample based on their mean Ct values.

The advantages of using a standard curve are as follows: (1) you have a direct measure of the assay quality for each plate or group of samples and (2) data can be compared from plate to plate with confidence. Disadvantages are as follows: (1) care must be taken to ensure the standard curves for each assay are reproducibly made from run to run and (2) standard curves take up wells on the plate that could be used for unknown samples.

There are many examples where using a standard curve to determine a value for unknown samples is preferred. One would be in screening patients for a pathogen. Knowing the pathogen is present early in an infection would be very useful. Equally useful would be to know how many pathogens are present. This added knowledge would be very helpful in determining how aggressively the patient should be treated. Another example would be a large study with many animals or tissue culture plates involving controls, multiple test agents, and multiple transcript assays. Having a quantitative value for each transcript provides great flexibility in how data will be analyzed utilizing a variety of statistical methods.

7.4 Quantification Using the ddCt Method

Not all studies require that a specific value, interpolated from a standard curve, be determined for each sample. Rather, the goal of the experiment is to simply calculate a fold difference between one sample against the remaining samples on the plate or a group of similar control samples compared to one or more

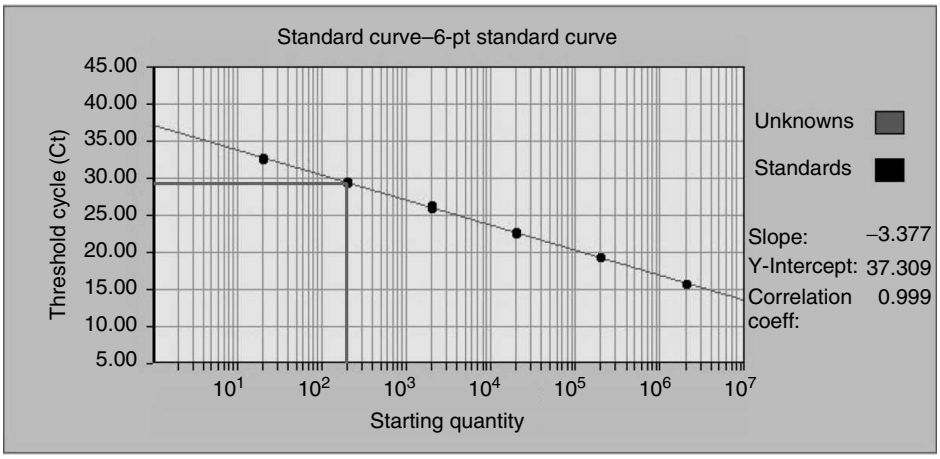

Fig. 11 A 6-log standard curve with a graphic demonstration of how the software determines molecules from the Ct values measured by real-time instruments. A Ct (threshold cycle) value of approximately 29.5 (*y*-axis) would result in an interpolated value of 200 molecules (*x*-axis) using this standard curve. A change in the slope of the curve or the measured Ct values of the standards would change the number of molecules obtained from the same Ct reading (see color plate p. xxxvi).

experimental groups on the plate. For these studies, there is a way to calculate a fold difference directly from the Ct values obtained from the real-time PCR data. A second assay, using an invariant housekeeping transcript or one of the ribosomal transcripts, must be performed to normalize the data for differences in sample loading. Armed with the Ct values from the transcript of interest and one used for normalization, a method called the delta delta Ct determination or ddCt can be employed.

As the name implies, the deltas involve subtraction steps. The first is to subtract the Ct of the assay used for data normalization from the Ct of the assay of interest. This now gives a normalized Ct value for each sample on the plate as follows:

Housekeeping gene assay
Sample 1 − Ct = 21.5
Sample 2 − Ct = 20.9
Sample 3 − Ct = 21.2

Gene of interest
Sample 1 − Ct = 25.2
Sample 2 − Ct = 22.7
Sample 3 − Ct = 21.4

Therefore, the deltaCt, normalized for loading for each sample is as follows:

Sample 1 = 3.7
Sample 2 = 1.8
Sample 3 = 0.2

Let us assume that, in this experiment, we want to know the fold difference of Samples 2 and 3 compared to Sample 1. We then have to subtract again, for the second delta:

$$\text{deltaCt S2} - \text{deltaCt S1} = 1.8 - 3.7 = -1.9$$

$$\text{deltaCt S3} - \text{deltaCt S1} = 0.2 - 3.7 = -3.7$$

Relative fold difference can be determined by the formula, 2^{-ddCt}

$$\text{Sample 2 relative to Sample 1} = 2^{-(-1.9)} = 3.73 \text{ fold}$$

$$\text{Sample 3 relative to Sample 1} = 2^{-(-3.7)} = 13.00 \text{ fold}$$

Advantages of using the ddCt method are as follows: (1) you do not have to run a standard curve on each plate and (2) the calculation is easy to perform. Disadvantages are as follows: (1) there is no direct evidence each plate has run as expected (slope); (2) comparing data from plate to plate must be controlled by a common sample(s); and (3) final data can only be expressed as a fold difference.

The ddCt method works very well for large studies where there are many samples being compared to a common control. One example of this kind of assay could be the screening of a small molecule library where assaying a maximal number of compounds in each assay set is critical for throughput. The purpose of such a screen could be to find the most active compounds affecting a target transcript from a biological pathway. Comparing this data with another screen utilizing another target transcript from a second pathway might aid in the selection of a compound that has selective activity; high in one assay and low in the second. Those that fit the criteria of the screen would then be moved on to other assays to confirm and elaborate the findings of the real-time PCR screen.

8 Future Directions

Since the inception of real-time PCR by ABI in 1996 with the 7700, the footprint of newer instruments has been steadily getting smaller, the cost has fallen from about $100 000 per machine to about one-quarter of that price, and, in some ways, the newer machines are better than the original. Not only can you get high quality data for less money but the software is also more sophisticated in assisting the user in analyzing and presenting the data. The result of the smaller sizes and lower cost points is that these instruments are migrating from the domain of the core laboratory into individual research laboratories at an increasing rate. The only problem with this trend is that the companies selling real-time PCR instrumentation are not keeping up with training and/or the training is inadequate. The rapid increase in instruments in individual laboratories will put even more pressure on companies selling real-time PCR instruments. Hopefully, this review has provided enough of an introduction to the technique to at least make the reader aware of the major issues involved in performing real-time PCR correctly.

One thing the newer real-time instruments excel at is multiplexing. The hardware has evolved to the point that selective collection of fluorescent light over the entire green–red spectrum is now possible. There are multiple fluorescent dyes available within this broad range capable of being used as reporters covalently attached to fluorescently labeled primers or probes. However, assay design software currently on the market is only capable of designing assays that work in isolation. One way of keeping down costs and saving time would be to obtain information on the assay of interest as well as information for a second transcript useful for data normalization, design two compatible assays, and then run them together in the same, multiplexed reaction. The ability of the

investigator to design good multiplexed assays in the same way that single assays can be made, presently, has not kept up with the hardware. Assay design software and the commercial sector will have to catch up with the currently available instrumentation before multiplexing becomes a true advantage to the consumer. Fortunately, there are promising signs of new software for multiplexing on the horizon.

The real value of real-time PCR instruments is their ability to collect data over time. It is this temporal component that adds an invaluable dimension to the data set. It would seem logical then that these instruments could be used for more than studies utilizing nucleic acids or, at the least, more than just PCR. There may be a number of assays that are currently read at end point, that would be amenable to the detection capabilities of a real-time instrument, and could benefit from the addition of a temporal component. One challenge yet unmet by manufacturers of real-time instruments is to expand the use of these instruments to other facets of investigation beyond PCR.

Keywords

Allosteric Switch
A glutamine residue conserved in all RecA superfamily proteins that interacts with the γ-phosphate of bound ATP and triggers conformational changes that contribute to formation of the active form of the protein filament.

ATP Cap
A loop formed by 6 to 7 residues that extends into the ATP binding site of the neighboring subunit to make contacts that are likely involved in stabilizing the structure of the filament and perhaps transmitting ATP-induced allosteric information across the subunit interface.

C-terminal Gateway
A domain formed by the C-terminal region of RecA proteins involved in regulating access of double-stranded DNA into the core of active RecA/ssDNA/ATP filaments.

Helix-hairpin-helix motif
A domain typically involved in non-sequence-specific DNA binding found in the N-terminal region of RadA and Rad51 proteins that may regulate binding of double-stranded DNA in a manner similar to the C-terminal gateway in RecA proteins.

Holliday Junction
The X-shaped crossover structure resulting from the action of RecA-like proteins during the ''homologous pairing and strand exchange'' step in the HR pathway. This type of structure had been proposed as an intermediate in the HR pathway by Robin Holliday in 1964.

Homologous Recombination (HR)
The transfer of genetic information between two double-stranded DNA molecules of similar sequence that results from a physical exchange of DNA strands.

N-terminal Polymerization Motif
A short β-strand that forms a section of the oligomeric interface by interacting with another β-strand in the core region of the neighboring subunit. This motif is conserved in all RecA superfamily structures solved to date, as well as in the human BRCA2 protein where it likely serves to regulate assembly of Rad51 filaments at the site of a DNA break.

Rad51-mediator Activity
First described for the yeast Rad52 protein regarding its ability to assist Rad51 filament formation, this function now appears to have been conserved in all organisms in which RecA/Rad51-mediated recombination occurs. Examples include RecFOR/RecA and BRCA2/human Rad51 interactions.

Translesion Bypass
DNA replication catalyzed by an error-prone polymerase across a damaged region of template DNA. Specific protein–protein interactions between RecA and the polymerase at the site of damage are important to optimal polymerase function.

The bacterial RecA protein is the central component in both the catalysis of homologous recombinational DNA repair and the regulation of expression of a family of DNA repair genes. It functions in a number of mechanistically distinct processes, all of which contribute to the maintenance of genomic integrity, and all of which require formation of an active RecA/ATP/DNA complex. As cellular, biochemical, and structural studies of the eukaryotic and archaeal RecA homologs progress (Rad51 and RadA, respectively), it is clear that despite fundamental similarities in the mechanism of DNA strand exchange catalyzed by both proteins, there are distinct differences in their catalytic mechanisms as well as dramatic differences in the cellular pathways in which each protein plays important roles. For example, both RecA and the human Rad51 protein require ATP binding and hydrolysis for the catalysis of DNA strand exchange, but the use of ATP is distinctly different for each protein. Additionally, whereas RecA plays a specific role in transcriptional regulation of DNA repair genes, no such activity is seen for Rad51. In this review, we offer a comparative view of the biochemical functions of RecA and Rad51, with a particular focus on descriptions of our current understanding of the molecular design, catalytic organization, and allosteric regulation of enzyme function.

1 RecA: Function in Homologous Recombination

The bacterial RecA protein participates in a remarkably diverse set of biological functions, all of which contribute to the maintenance of genomic integrity during the lifetime of the organism as well as to ensure that genetic information is transmitted to subsequent generations with high fidelity. Bacterial RecA is directly responsible for (1) regulation of expression of a set of DNA repair genes referred to as the SOS regulon; (2) catalysis of DNA strand exchange; and (3) promoting bypass of DNA lesions by a specialized DNA polymerase during a cell's recovery from DNA damage. There are RecA-like proteins in all free living organisms, and, in all cases, their recombination function plays an important role in the repair of damaged DNA, whether the damage results from inherent errors in the machinery responsible for replicating DNA, or from exposure to exogenous mutagens. In fact, in their search for mutants that showed defects in homologous recombination (HR), Clark and Margulies discovered in 1965 that defects in *recA* greatly increased the sensitivity of bacteria to the DNA-damaging effects of UV light, thus establishing the link between homologous recombination and DNA repair. The primary enzymatic function of RecA-like proteins is the catalysis of HR. This involves exchange of genetic information between DNA molecules of similar sequence, a process resulting from the physical transfer of DNA strands. The HR pathway is traditionally broken down into four steps as seen in Fig. 1, and RecA-like proteins specifically catalyze the ''homologous pairing and strand exchange'' step, thus creating crossover structures known as *Holliday junctions* (named after Robin Holliday). In the scheme depicted in Fig. 1, the ''initiation'' step involves processing double-strand DNA breaks by exonucleases. In bacteria, this is accomplished by the RecBCD enzyme, but the mammalian counterpart(s) have not yet been identified. This leaves an ssDNA tail that serves as substrate for RecA proteins. ''Pairing and strand exchange'' results when the RecA/ssDNA complex invades a homologous duplex DNA, for example, a sister chromatid. The RecFOR complex is indicated at this step, but current work indicates that this complex regulates assembly and disassembly of the RecA filament specifically during repair of DNA gaps, as described below. The RecA protein itself can perform ''branch migration,'' but, *in vivo*, this process is carried by specialized motor proteins, for example, the bacterial RuvAB helicase complex. Again, although there are a number of candidate helicases in mammalian cells, the one(s) responsible for branch migration of Holliday crossovers have yet to be identified. ''Resolution'' is achieved by the action of structure-specific endonucleases (''resolvases''), and, in bacteria, this function is performed by the RuvC protein. In mammalian cells, the Rad51C/Xrcc3 protein complex has been shown to be associated with Holliday junction resolvase activity, but it is currently unclear if one of these proteins or an associated nuclease is responsible for junction cleavage.

1.1 RecA: Structure and History

The first X-ray crystal structure of the *Escherichia coli* RecA protein was solved in 1992 by Story et al. In this work, the structures solved were that of protein alone and the protein–ADP complex. In both cases, RecA formed a helical filament

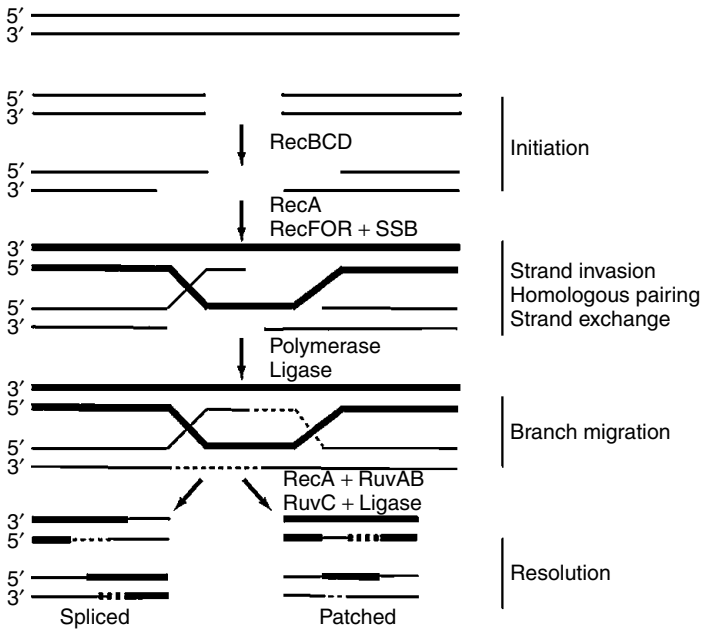

Fig. 1 Steps in the homologous recombination pathway. A basic model for homologous recombinational repair of DNA double-strand breaks (DSBs) in *E. coli* that can be separated into four major steps and are described in the text. The function of RecA in ''homologous pairing and strand exchange'' is the primary focus of this review.

with six subunits per turn and a distance between turns (pitch) of approximately 83 Å. Previous electron microscopic investigations had clearly established that the RecA filament could exist in two distinct oligomeric states, an ''inactive'' and ''active'' filament. The inactive filament is formed by RecA in the absence of nucleotide or by a RecA/DNA/ADP complex and has 6.2 subunits per turn with a pitch of approximately 68 Å. The active RecA filament forms in the presence of DNA and ATP, also has 6.2 subunits per turn but has an extended pitch between 95 and 100 Å. Because the RecA crystal structure contained ADP and has a pitch intermediate between the inactive and active filament, it was not clear what aspects reflected the structure of an active RecA filament. Since that time, many groups have attempted to solve the structure of a catalytically active RecA/DNA/ATP complex, but with no success. Therefore, the original RecA structure has served for more than a decade as a model for the design of experiments aimed at characterizing the molecular mechanism of HR. During this time, and now with the availability of new structures of archaeal RadA and eukaryotic Rad51 proteins, a more complete picture is emerging regarding the structural dynamics of RecA-like filaments, and the relationship of filament structure to its catalytic function.

This review focuses on our current understanding of the structural design of the bacterial RecA protein, the functional coordination of its various domains, and

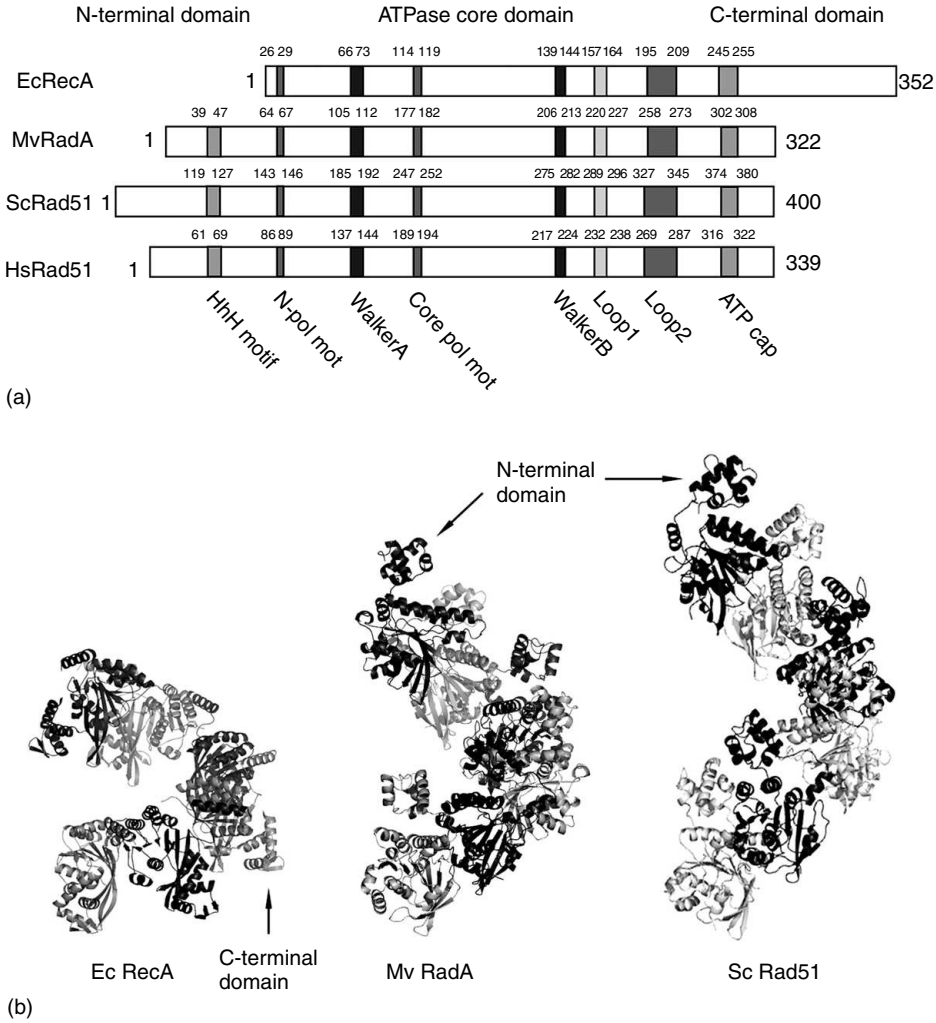

Fig. 2 Domain maps and filament structures of RecA superfamily proteins. (a) Domain map alignment of EcRecA, MvRad51, ScRad51, and HsRad51. HhH, helix-hairpin-helix; N-pol mot, N-terminal polymerization motif (see text). (b) One helical turn (6 subunits) of EcRecA, MvRadA, and ScRad51 protein filament with alternating subunits shown in dark and light colors. These filaments are arranged so that the N-terminal domain (MvRadA and ScRad51) is shown on top, and C-terminal domain (RecA) is positioned at the bottom, as indicated by arrows. Images are made from PDB files: 1REA, 1T4G, and 1SZP.

how new structures of RecA-like proteins now provide important insights into the catalytic organization of these recombinase enzymes. The alignment in Fig. 2(a) indicates some of the conserved domains within RecA, RadA, and Rad51 proteins that will be discussed below. Each member of the RecA superfamily contains the consensus Walker A and B ATP binding site motifs, and recent structural analysis of

RadA and Rad51 proteins reveal a new motif referred to as the *ATP cap* that appears to play important roles in ATP binding and cross-subunit communication. The L1 and L2 domains, as well as the extended C-terminus of RecA and N-terminus of RadA and Rad51, are discussed in terms of their roles in DNA binding. Given the fact that all of these proteins form head-to-tail polymers, large areas of the protein surface are involved in formation of the subunit interface. However, one region, in particular, the N-terminal polymerization motif, deserves mention because of its structural conservation across all members of the superfamily, and especially because of its potential role in specifically regulating Rad51 assembly in human cells.

2
ATP Binding and Hydrolysis

2.1
The Walker A motif

RecA is a DNA-dependant ATPase and contains the traditional Walker A and Walker B sequences that are found in most NTP-requiring enzymes. The Walker A motif, whose consensus sequence is defined as GXXXXGK(T/S), is also known as the P-loop because it contains residues that interact with the phosphate groups of bound NTP. In *E. coli* RecA, this motif extends from residues 66 to 73, and the highly conserved GPESSGKT sequence is identical in 61 of 64 bacterial RecA proteins. Despite this high degree of sequence identity, only four residues have been shown to be absolutely critical to RecA function: Gly66, Gly71, Lys72, and Thr73. In all currently available X-ray crystal structures of RecA proteins, the P-loop lies on the inside surface of the protein filament and near, but not directly within, the subunit–subunit interface. Although numerous mutant RecA proteins have been created with substitutions in the P-loop, work with one mutant, in particular, (Lys72Arg) has provided significant insight into important aspects of the catalytic mechanism of RecA. Although this substitution inhibits ATP hydrolysis, but not binding, and blocks recombination activities *in vivo*, the purified protein still catalyzes strand exchange up to 1.5 kb pairs. This established the idea that ATP binding, rather than ATP hydrolysis, induced a conformationally active form of RecA. Later studies using this same mutant protein showed that ATP turnover is important for coupling the exchange of subunits between free and bound states with further progression of strand exchange.

2.2
The Walker B motif

The Walker B motif in *E. coli* RecA extends from residues 139 to 144 with Asp139 and Asp144 flanking four hydrophobic residues. Although the function of Walker B motifs are less well defined than Walker A and may differ depending on the specific protein, they are most frequently thought to assist in coordinating Mg^{2+} in the bound Mg^{2+} –NTP complex via an Asp residue, play roles in transmitting ATP-induced allosteric information between proteins domains, or, in some cases, may be directly involved in ATP-mediated DNA binding. In the RecA crystal structure, Asp144 binds the Mg^{2+} in the ATP site and is identical in 64 of 64 RecA sequences. Asp139 lies within the subunit interface and is seen in the RecA structure to make a cross-subunit ionic contact with Lys6. However, the relevance of this

interaction to the active form of RecA has been questioned because substitution of various polar and nonpolar amino acids for Asp139 has no deleterious effects on RecA function. A five-residue sequence following the Walker B motif, residues 145 to 149, is identical in 63 of 64 RecA sequences, and analysis of *Mycobacterium tuberculosis* RecA in complex with various NTPs suggests that this ''connector'' segment serves to link the L2 and L1 regions, both physically and functionally upon binding of NTP, thus playing a role in coordinating the primary and secondary DNA binding sites of RecA.

2.3 The ATP Cap

Recently solved structures of archaeal RadA proteins and yeast Rad51 now provide new and interesting insights into the arrangement of residues at the subunit interface that may be important for stabilizing the binding of ATP and regulating ATP-induced allosteric effects within the protein filaments. The archaeal *Methanococcus voltae* RadA structures were solved in the presence of the nonhydrolyzable ATP analog (AMP-PNP) and form a filament with six subunits per turn and a pitch of approximately 104 to 107 Å. This pitch approximates what has been determined to be the pitch of the active form of RecA. In these structures, the subunit interface near the ATP binding site shows significant differences relative to the arrangement of residues in currently published RecA structures. These MvRadA structures reveal a previously uncharacterized structural region, referred to as the ''ATP cap,'' in which residues from one subunit make specific contacts with the ATP in the binding site of the neighboring subunit. The ATP cap in MvRadA spans residues 302 to 308 and one particularly notable feature is Pro307, which stacks directly against the purine base of AMP-PNP (Fig. 3). Remarkably, this Pro is conserved in all RecA superfamily proteins, including all bacterial RecAs currently sequenced. Other residues in the ATP cap are in close contact with the neighbor's AMP-PNP. For example, Asp302 forms a hydrogen bond with the hydroxyl proton at the 3'position of ribose as well as several water-mediated hydrogen bonds with phosphate oxygen at the α and β positions of AMP-PNP. Interestingly, the equivalent residue in *E. coli* RecA is Lys248, which could make similar bonding interactions with the neighboring ATP. A Lys248Ala inhibits RecA function by disrupting the stability of the protein filament. The new yeast Rad51 structure forms a filament with a pitch of 130 Å, which is within the limits seen by electron microscopy for active RecA/ATPγS/dsDNA filaments. Although crystallization solutions contained ATPγS and a 96-base poly-dT oligonucleotide, only a sulfate ion was observed in the ATP binding site in a position that would be occupied by the β-phosphate of bound ATPγS. Importantly, a region equivalent to the ATP cap in MvRadA is seen to extend into the ATP binding site of the neighboring subunit, and Pro379 is in virtually the same position as the equivalent Pro307 in the MvRadA structure (Fig. 3).

When considering how these new RadA and Rad51 structures may relate to RecA, it is important to note the model proposed by VanLoock et al. In this study, the authors performed a rigid body rotation of a subunit in the RecA crystal structure and manually docked the subunit volume into a reconstruction of the active form of

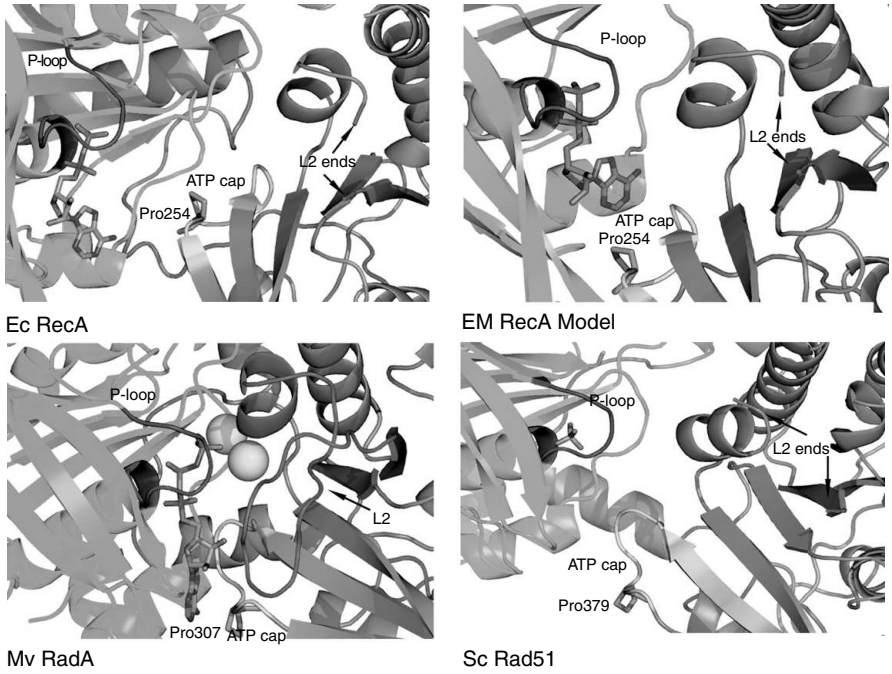

Fig. 3 ATP binding region and the "ATP cap." This view of subunit interface is seen from the inside of the filament. The ribbon diagram of the α-carbon backbone is blue for one subunit and green for the neighbor. In the green subunit, the Walker A motif, or P-loop, is in red, and the following ligands are seen bound to this motif: ADP in EcRecA and EcRecA model; AMP-PNP in MvRadA; a sulfate ion in ScRad51. In the blue subunit, the L2 region (MvRadA) or residues that flank L2 (other 3 panels) are in pink, the "ATP cap" is in yellow, and its universally conserved Proline is in orange. The yellow spheres in the MvRadA structure correspond to two K^+ atoms that are bound to the AMP-PNP. Images are made from PDB files: 1REA, 1N03, 1XU4, and 1SZP (see color plate p. xxxvii).

the RecA filament derived from analyses of electron micrographs. The resulting structure showed an arrangement of subunit–subunit interactions, very similar to those seen in the new RadA and Rad51 structures, and the region that would be the RecA ATP cap is shown in Fig. 3.

2.4 ATP Hydrolysis

While the binding of ATP induces a conformationally active form of RecA, the mechanistic requirement for ATP hydrolysis is still the subject of ongoing studies. Two important features of RecA-mediated strand exchange that require ATP hydrolysis are the ability to progress in a directional fashion and to bypass a variety of DNA lesions or certain lengths of heterology. A recent review of the motor activity of RecA describes models for the coupling of ATP hydrolysis and strand exchange. In the structures of RecA, Glu96 is positioned within the ATP binding site such that it can promote hydrolysis of ATP to ADP, and mutational analysis supports this role. Although both the yeast

and human Rad51 proteins are DNA-dependent ATPases, the mechanistic steps required for ATP binding and hydrolysis are not yet well understood (see Sect. 5: Allosteric Mechanism).

3 DNA Binding Domains

3.1 Loop1 and Loop2

To carry out the process of DNA strand exchange, RecA and Rad51 filaments must bind both, an ssDNA substrate and the homologous duplex DNA. Despite the availability of several new crystal structures for RecA, RadA, and Rad51 proteins, none has included a DNA substrate. Therefore, detail regarding the specific interactions between protein and DNA is still lacking. However, a number of mutagenesis and biochemical efforts have provided a good understanding of domains within the RecA protein that bind DNA and their positions within the filament structure. On the basis of the original RecA structure, Story et al. proposed that two disordered regions were likely to be the primary (or ssDNA) and secondary (or dsDNA) binding sites. Loop 2 (L2) extends from residues 195 to 207 and is considered to be the primary DNA binding site, while loop 1 (residues 157–164) is considered to be part of the secondary DNA binding site (Fig. 4). L2 lies within the inner surface of helical filament structure, while L1 is seen on the top surface of the filament (Fig. 4). Some studies suggest that the L2 and L1 DNA binding domains may interact both physically and functionally, and a ''connector'' segment extending from residues 145 to 149 may be specifically involved in transmitting NTP-induced structural changes in L2 to L1. The extensive number of biochemical, mutational, and structural studies giving rise to the current model of DNA binding by the RecA protein have been reviewed recently. Interestingly, the MvRadA structures reveal a much closer physical approach of the L2 and L1 regions than is seen in the RecA structures (Fig. 4). Therefore, if the MvRadA structures do reflect the active form of the protein filament, it would support the very reasonable idea that the primary and secondary DNA binding sites are likely to interact both physically and functionally during the catalysis of DNA strand exchange.

3.2 C-terminal Gateway

In the currently available RecA structures, the C-terminal 25 residues are unresolved, but biochemical studies suggest that this region of the protein serves as a ''gateway'' that regulates the accessibility of dsDNA to its DNA binding site. Further work suggests that a network of salt bridges in this region precludes access of dsDNA to the filament interior, and increasing Mg^{2+} disrupts these interactions thereby opening the ''gateway.'' How this might be accomplished *in vivo* remains to be determined.

3.3 Eukaryotic and Archaeal Uncertainty

While the identity and position of DNA binding domains within various RecA proteins is now fairly well-modeled, the DNA binding domains within the eukaryotic RadA and Rad51 proteins are currently not well defined. The L2 region of HsRad51 includes residues 270 to 287 and lies near the filament axis. However, mutagenesis studies suggest that L2 is not involved in

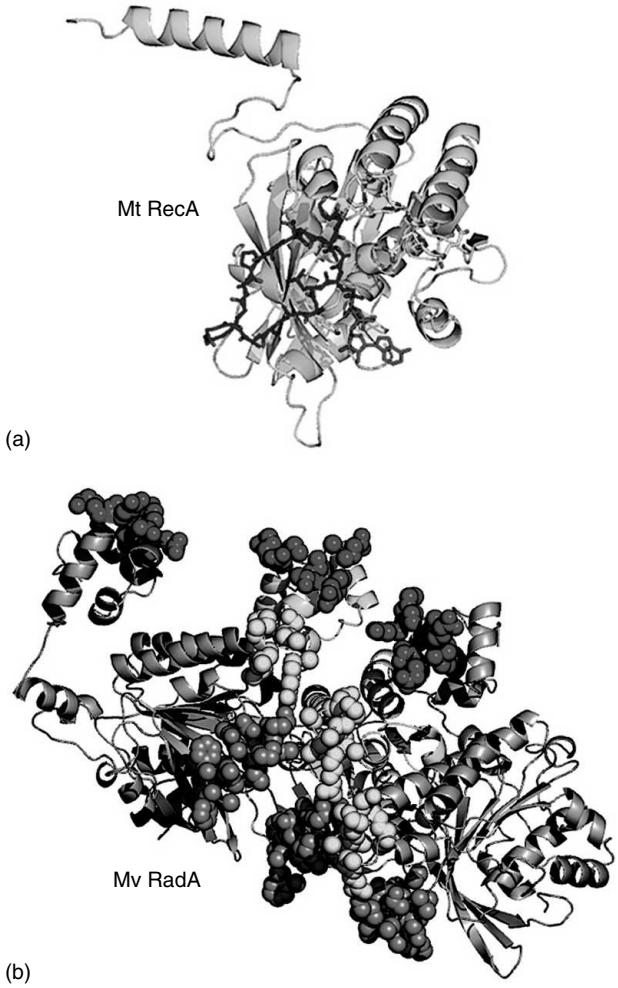

Fig. 4 DNA binding domains of RecA and RadA. (a) Monomer of MtRecA, with the L1 and L2 DNA binding regions shown in yellow and blue respectively. (b) A trimer of MvRadA as seen from the inside of the filament, showing amino acid side chains of L1 (yellow), L2 (blue) and the N-terminal Helix-hairpin-Helix domain (red) as space-filling spheres. Images are made from PDB file: 1G18/1G19 and 1XU4. The green MtRecA subunit (a) is in approximately the same orientation as the green MvRadA subunit (b) (see color plate p. xxxviii).

binding to ssDNA. We have recently created mutant HsRad51 proteins carrying either multiple or single Ala substitutions throughout the L2 region and find that all mutant proteins bind ssDNA with an affinity similar to wild-type HsRad51. Therefore, it seems that the L2 region in HsRad51 does not serve the same function

as L2 in RecA. In contrast, several mutant HsRad51 proteins with Ala substitutions in the L1 region (residues 231–239) show significant decreases in binding to ssDNA.

3.3.1 Helix-hairpin-helix

Relative to the bacterial RecA proteins the eukaryotic and archaeal Rad51 and RadA proteins have an extended N-terminus that contains a helix-hairpin-helix motif (''HhH motif'' in Fig. 2a; HsRad51 residues 61–70). NMR chemical shift perturbation mapping of this region suggests that it has a role in directly binding dsDNA in HsRad51. Crystal structures of Rad51 and RadA filaments show that this region is positioned along the upper surface of the filament and could serve as the dsDNA binding domain or be involved in regulating access of dsDNA to the filament interior similar to the C-terminal region of RecA (Fig. 2b, Fig. 4).

4 Oligomeric Interface Domains

The oligomeric form of RecA-like proteins required for the catalysis of DNA strand exchange is an extended helical polymer that wraps around ss- and dsDNA, making contact with the nucleic acid polyphosphate backbone, but not the bases. Formation of the nucleoprotein filament extends the helical pitch of dsDNA from an axial rise per base pair of 3.4 Å (standard B-form dsDNA) to 5.2 Å. These DNA binding properties of RecA led to the idea that one of the primary functions of RecA-like proteins was to reveal the DNA bases in a way that optimizes strand switching and formation of new Watson–Crick bases pairs during the catalysis of strand exchange.

4.1 N-terminal Polymerization Motif

The first crystal structure of *E. coli* RecA revealed an extensive surface on each side of the subunits that formed the oligomeric interface. Earlier genetic and biochemical studies had predicted that a domain in the extreme N-terminus of RecA played an important role in oligomer formation. Comparison of all RecA, RadA, and Rad51 structures now reveals a small conserved structural domain recently termed the *polymerization motif* by Shin et al. Not only is this motif important for the oligomeric stability of RecA-like proteins, in the case of human Rad51, it appears to play an important role in the BRCA2-mediated regulation of Rad51 nucleoprotein filament assembly at the site of DNA damage. The motif forms a short β-strand (''N-pol mot'' in Fig. 2a) that interacts in antiparallel fashion with a β-strand in the ATPase core (''Core pol mot'' in Fig. 2a) of the neighboring subunit (Fig. 5). Alignment of this conserved region in *E. coli* RecA and several eukaryotic RadA and Rad51 proteins is shown in Table 1. This region is highly conserved among 64 bacterial RecA sequences, and, although not well conserved with the equivalent sequences in eukaryotic RadA and Rad51 proteins, the structure is conserved among all RecA-like proteins. In the Pf Rad51 structure Phe97 and Ala100 interact with the neighboring subunit through contacts with

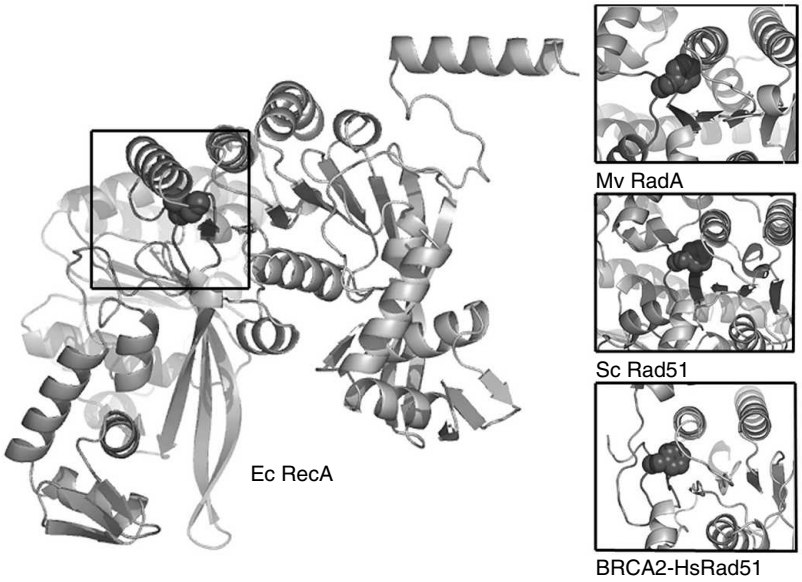

Fig. 5 N-terminal Polymerization motif. The left-hand image is two subunits of the EcRecA filaments (viewed from the outside surface of the filament), showing the N-terminal polymerization motif (green) and the Core Polymerization Motif (red). Isoleucine 26 is shown in space-filling spheres. The boxes on the right show the equivalent interface region in MvRadA (Phe64), ScRad51 (Phe144), and the BRC4-HsRad51 fusion protein (Phe1524) with indicated phenylalanine residues interacting with the neighboring subunit. Images were made from PDB files: 1REA, 1XU4, 1SZP and 1NOW (see color plate p. xxxix).

hydrophobic regions, and similar cross-subunit interactions are observed for the conserved residues in the ScRad51 and MvRadA. Mutational analysis of the equivalent residues in HsRad51, Phe86 and Ala89, supports the idea that both are important for oligomer stability. Further support for the idea that this region is an important part of the oligomeric interface comes from fluorescence studies of Xenopus Rad51. The structure of an HsRad51-BRC4 fusion protein gave rise to the idea that the BRC repeats in BRCA2 interact with Rad51 by mimicking the N-terminal polymerization motif surface. The alignment in Table 1 shows that Phe1524 and Ala1527 in the BRC4 repeat are conserved in this motif. Examination of the *E. coli* RecA, MvRadA, ScRad51, and HsRad51-BRC4 protein structures shows a striking similarity in cross-subunit interactions in this region of the interface, highlighted by insertion of a conserved Phe or Ile into a hydrophobic area of the neighboring subunit (Fig. 5). Further details of the mechanism by which the BRCA2 protein regulates assembly of HsRad51 nucleoprotein filaments at the site of DNA damage is provided in a recent review by Pellegrini and Venkitaraman.

4.2 Other Cross-subunit Contacts

Residues involved in making cross-subunit contacts account for a high

percentage of the conserved residues seen in 64 bacterial RecA sequences. Roca and Cox noted a highly conserved region corresponding to residues 214 to 222 in *E. coli* RecA that they termed a *RecA signature sequence*. In this stretch, 5 of the 9 residues are identical in 64 bacterial RecA sequences (Ala214, Leu215, Lys216, Phe217, Arg222) and the other positions show a high degree of chemical conservation. Modeling studies of *E. coli* RecA and the crystal structures of the RadA and Rad51 proteins support the idea that this region of the interface is more extensively involved with direct contacts with the ATP binding site in the neighboring subunit than the original RecA structure revealed. This region will be discussed in greater detail in the Sect. 5: Allosteric Mechanism.

5
Allosteric Mechanism

5.1
Allosteric Switch: Gln194

Early biochemical studies of RecA showed that ATP serves as an allosteric effector of enzyme function, that is, its binding causes RecA to become catalytically active. For example, although RecA binds with low affinity to ssDNA in the absence of ATP, its DNA binding affinity is increased dramatically in the presence of ATP or a nonhydrolyzable analog such as ATPγS. The RecA crystal structure shows that Gln194 is positioned within the ATP site near to where the γ-phosphate of bound ATP would be, and, therefore, may serve as the sensor of ATP binding. Mutational and biochemical studies confirmed that Gln194 is indeed an ''allosteric switch'' that triggers conformational changes within the protein in response to ATP binding, an action that is critical for RecA function (see below). Subsequent studies suggested that Gln194 also plays a more direct role in ATP hydrolysis in a manner similar to G-proteins.

5.2
ATP Sensing: Phe217

Large-scale mutagenesis efforts identified Phe217 as a critical subunit interface residue involved in transmitting ATP-mediated allosteric information throughout the oligomeric filament structure. Of 15 different substitutions at Phe217, only Tyr maintained wild-type-like activity *in vivo*, while all others were significantly inhibited. Biochemical studies showed that the Phe217Tyr substitution resulted in a hypercooperativity mutant that increased the kinetics of ATP-induced filament assembly by more than 250-fold. Together with other mutagenesis studies, these data suggested that the following molecular events occur within the RecA structure upon ATP binding. The interaction of Gln194 with the γ-phosphate of ATP triggers a conformational change in the L2 region (residues 195–209). Glycine residues at positions 211 and 212 are nonmutable, and, undoubtedly, are critical to propagating the conformational change into a small helix immediately downstream of L2 (residues 213–218). This results in a specific movement of Phe217 toward the neighboring subunit. However, in the original RecA crystal structure, it was not apparent what residues in the neighbor might interact with Phe217. Subsequent modeling studies using image analyses of electron micrographs suggested that subunits in the active RecA filament are reoriented such that Phe217 and other nearby side chains, for example, Lys216

and Arg222, lie very close to the ATP binding site of the neighboring subunit. In fact, the structures of MvRadA and ScRad51 show that this is likely the case (Fig. 6). The MvRadA/AMP-PNP structure, solved in potassium-rich media, shows that the NTP sits directly within the interface between two subunits. His280, which aligns with *E. coli* RecA Phe217, makes a hydrogen bond with the γ-phosphate of AMP-PNP in the neighboring subunit (Fig. 6). A similar arrangement is seen in the ScRad51 structure in which His352 (equivalent to RecA Phe217 and MvRadA His280) lies close to a sulfate ion in the ATP binding site of the neighboring subunit (sulfate results from slow hydrolysis of ATPγS; Fig. 6). In this study, a His352Ala mutant was shown to be inhibited for ssDNA binding, thereby supporting the model in which His352 is important for formation of a filament that is competent for Rad51 function. Interestingly, when MvRadA was crystallized in low potassium media, the details of side chain conformations at the interface differ, in that access to the neighboring ATP binding site by His280 is blocked by Phe107 (Fig. 6). Similarly,

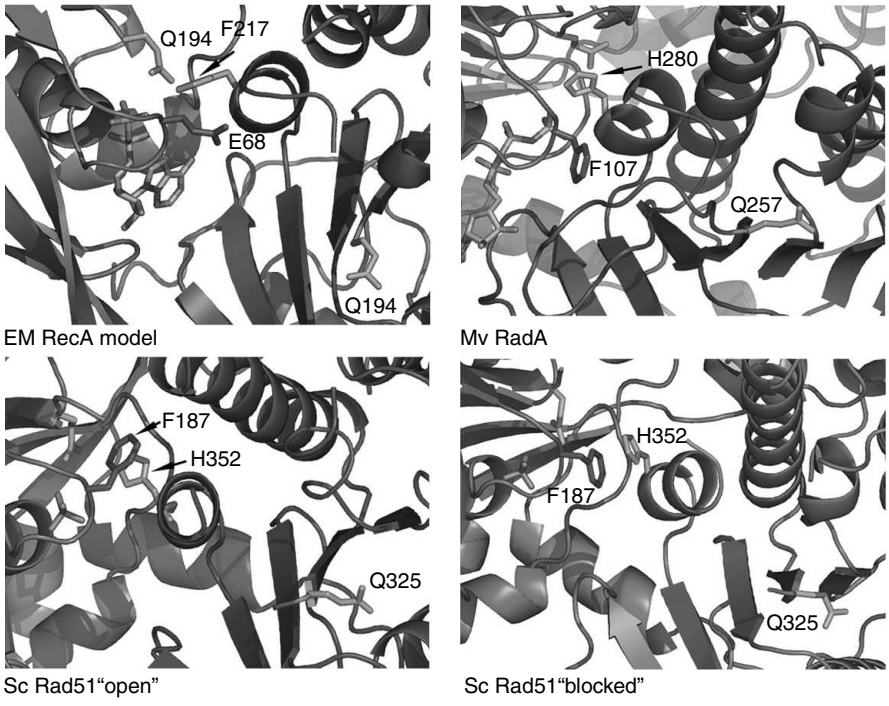

Fig. 6 Allosteric mechanism. Four panels showing different conformations of residues important in sensing ATP binding and conformational change of the filament structure. Glutamine 194 (EcRecA) and its homologous residues in MvRadA (Gln257) and ScRad51 (Gln325) are shown in yellow, while Phe217 (EcRecA) and the homologous histidine residues (MvRadA, His280; ScRad51, His352) are shown in purple. Glutamate 68 (EcRecA) and equivalent phenylalanine residues are in red. The region between Q194 and Phe217 (loop2) is unstructured in all but MvRadA. Images are made from PDB files: 1N03, 1XU4, and 1SZP (see color plate p. xl).

alternating interfaces in the ScRad51 structure show that His352 is blocked from interacting with the neighbor's ATP site by Phe187 (equivalent to MvRadA Phe107). These results may be indicative of the inherent flexibility within a RecA or Rad51 filament as it progresses through the cycle of ATP binding and hydrolysis during the catalysis of DNA strand exchange (see below). Therefore, given these new archaeal RadA and yeast Rad51 structures it seems likely that the positioning of bound ATP within the subunit interface contributes directly to subunit communication and to the cooperative nature of many aspects of recombinase function. A mechanistic similarity to other oligomeric ATPases, for example, DNA helicases, regarding the positioning of ATP binding sites has recently been described by Egelman. Although the contribution made by His280 in MvRadA and His352 in ScRad51 seems to involve direct hydrogen bonding with ATP in the neighboring subunit, it is currently not clear what kind of cross-subunit interactions are made by Phe217 in RecA. It is possible that Phe217 stacks with the purine ring of bound ATP, but further studies will be required to understand the specific molecular interactions of Phe217 in the active form of the RecA filament.

Despite a very similar arrangement of equivalent side chains in the ATP binding site and subunit interface, the human Rad51 protein shows a distinct difference regarding its use of ATP as an allosteric effector compared to RecA and yeast Rad51. Whereas RecA and ScRad51 require ATP to achieve a high-affinity ssDNA binding conformation, HsRad51 does not. It binds ssDNA cooperatively and with high affinity in the absence of ATP. This can be seen in Fig. 7, which shows biosensor DNA binding traces for *E. coli* RecA, ScRad51, and HsRad51. In this assay, protein is added directly to a cuvette containing immobilized ssDNA and binding of protein is measured in real time. Additionally, whereas a Gln194Asn or Gln194Ala mutation in RecA prevents high-affinity binding to ssDNA, equivalent mutations in HsRad51, for example, Gln268Asn, show no impairment of ssDNA binding. Although catalysis of DNA strand exchange by HsRad51 *in vitro* appears to be dependent on ATP hydrolysis, conflicting reports have appeared in the literature regarding the requirement for ATP hydrolysis for HsRad51 function *in vivo*. There are clear differences in the mechanisms by which various recombinase enzymes use NTP cofactors to drive catalysis of DNA strand exchange and further work will be required to fully understand these distinct requirements.

6 Proteins that interact with RecA

Although RecA shows proficient strand exchange activity *in vitro*, its activities *in vivo* depend on specific interactions with a variety of other proteins that are either directly involved in the catalysis of DNA repair or in the regulation of expression of DNA repair genes. Recent efforts have improved our understanding of both specific regions within the RecA protein structure responsible for these interactions as well as the functional consequences of these interactions.

6.1 RecBCD

The RecBCD enzyme is a highly processive helicase and nuclease whose activities undergo significant modification upon encountering a recombination hotspot

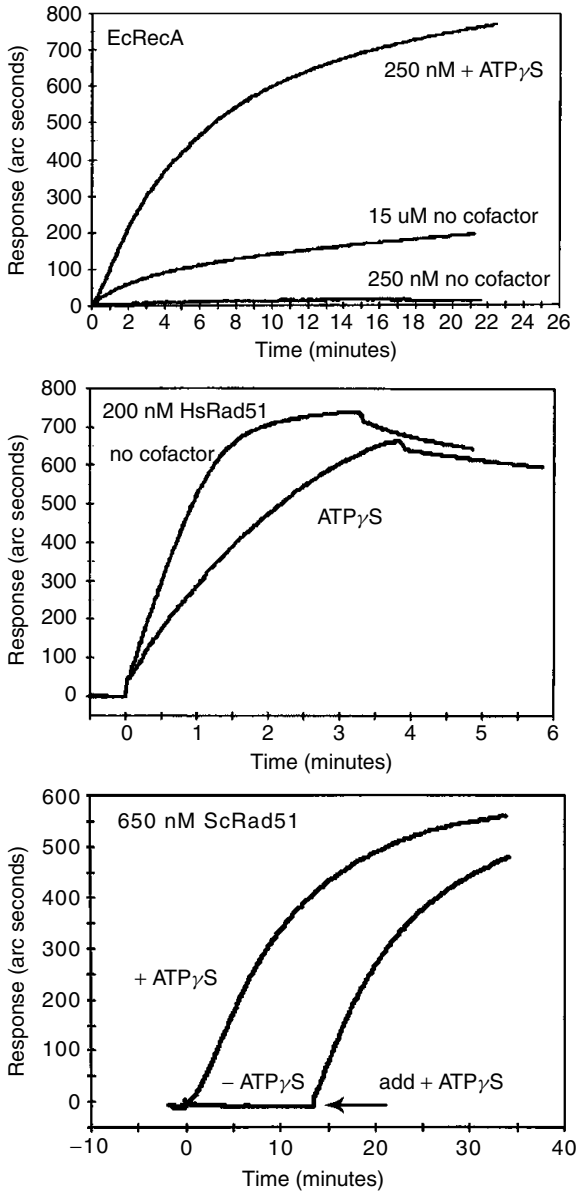

Fig. 7 Biosensor DNA binding data. These curves represent real-time binding of the indicated protein to ssDNA immobilized in an IAsys biosensor cuvette. The concentration of protein, as well as the presence or absence of nucleotide cofactor (ATPγS), is indicated in each panel.

known as *chi*. RecBCD generates 3'single-stranded ends that serve as a substrate for RecA binding and strand exchange. RecBCD also promotes loading of RecA onto ssDNA by virtue of a direct protein–protein interaction mediated by the C-terminal domain of RecB and some region of the core domain of RecA. The recently published X-ray structure of RecBCD now provides a clearer view of how the many activities of this enzyme are coordinated, as well as how the RecA loading site in RecB is likely revealed following RecBCDs encounter with *chi*.

6.2 RecF, O, and R

While early genetic studies suggested that the RecF, RecO, and RecR proteins play subtle, but important, roles in RecA-mediated recombination, recent studies show that they are specifically involved in RecA-mediated repair of gapped DNA lesions that frequently result when a replication complex stalls at a DNA lesion. It appears that these proteins can function both as subcomplexes as well as a heterotrimeric complex. RecFR and RecOR regulate the loading of RecA and the degree of RecA filament extension, respectively, within a gapped region. The RecFOR complex has been reported to serve as a structure-specific mediator of RecA by targeting recombinational repair to the ssDNA–dsDNA junctions in gapped DNA. Other studies support a role for RecFOR in clearing RecA from recombination intermediates to allow replication restart. Although no specific protein–protein interactions have been demonstrated between RecA and RecF, RecO, or RecR, studies by Bork et al. suggest that RecR specifically contacts RecA.

6.3 RecX and DinI

The *recX* and *dinI* genes are part of the SOS regulon and, through direct interaction with the RecA filament, serve to regulate RecA activity. In many bacterial species, the RecX protein is a negative modulator of RecA activity, inhibiting RecA ATPase, strand exchange, and coprotease activities, and serves to prevent harmful overexpression of RecA protein caused by DNA damage. However, in *Neisseria gonorrhoeae* RecX appears to be necessary for normal RecA function. Three-dimensional reconstructions of electron micrographs show that RecX binds to RecA nucleoprotein filaments by spanning the subunit–subunit interface, contacting the C-terminal domain of one subunit and the core domain of the neighboring subunit. However, recent studies show that the maximal inhibitory effect of RecX occurs at low, substoichiometric amounts of RecX relative to RecA. Drees et al. also show that RecX blocks extension of RecA nucleoprotein filaments through a proposed end-capping mechanism, resulting in a net filament disassembly. The interaction between RecX and RecA is modulated by the negatively charged C-terminal region of RecA, and is also enhanced by increasing Mg^{+} concentration.

Until very recently, DinI had been thought to be a negative regulator of RecA function, serving to attenuate the SOS response following DNA repair. However, new studies support the idea that the action of DinI opposes that of RecX and serves to stabilize active RecA nucleoprotein filaments. The inhibitory effects of DinI on RecA function occur only at elevated concentrations of DinI, whereas lower concentrations of DinI promote RecA activities. These studies have shown the

opposing effects of RecX and DinI to occur both *in vitro* and *in vivo*. Interestingly, at concentrations of DinI that stabilize RecA nucleoprotein filaments, RecA-mediated cleavage of UmuD is inhibited, whereas cleavage of LexA is not. DinI binds to the core domain of RecA and may specifically compete for UmuD binding, but not LexA. Additionally, the C-terminal domain of RecA modulates DinI function and provides regulated access to the core domain of RecA, perhaps in the same way that the C-terminal domain regulates access of dsDNA to the interior of the RecA filament.

6.4 Coprotease Substrates

The active complex of RecA/ATP/ssDNA also catalyzes the autoproteolytic inactivation of several repressor proteins, for example, LexA, phage λ cI and the phage ϕ80 repressors as well as the autoproteolytic activation of the UmuD protein. This activity has no mechanistic resemblance to the strand exchange activity of RecA, nor does it require extended nucleoprotein filaments. The original assumption was that RecA itself had a protease activity, but with the discovery by Little in 1984 that LexA and the phage λ cI repressors undergo a specific autodigestion reaction, it became clear that binding to RecA induced a conformation in these substrate proteins that was competent for autocleavage. Although binding sites for coprotease substrates within the RecA structure have yet to be specifically defined, a large number of mutagenesis, biochemical, and biophysical studies have provided strong evidence that the coprotease binding site includes specific positions within the groove of the RecA filament as well as positions on the upper surface of the filament that overlap with the L1 DNA binding domain. This subject and all of the studies leading up to this model have been reviewed recently by McGrew and Knight.

6.5 PolV

In addition to its activities as a strand exchange and coprotease enzyme, RecA participates directly in an important process referred to "translesion bypass DNA synthesis." The $UmuD'_2C$ complex (pol V) is an error-prone DNA polymerases in *E. coli*, and, as part of the recovery from DNA damage, pol V is activated to ensure that some of the unrepaired DNA lesions will not block DNA synthesis to an extent that kills the cell. Owing to its low fidelity, pol V gives rise to an increased level of mutations, and this process in bacteria has been termed *SOS mutagenesis* or *UV-induced mutagenesis*. RecA has several distinct roles in this process: (1) it serves to induce all SOS genes, including the *umuC* and *umuD* genes, by catalyzing autodigestion of the LexA repressor; (2) it catalyzes the autoproteolytic activation of UmuD to the active UmuD' form; (3) and it interacts directly with the $UmuD'_2C$ complex at the site of lesion bypass. The region of the RecA structure that interacts with $UmuD'_2C$ is located on the surface of the subunit interface that would be at the 3′ end of bound DNA, the end of the filament that will be facing the lesion needing to be bypassed by polV.

6.6 Proteins that Interact with Rad51

A number of proteins have been identified that interact with either yeast or human Rad51 using various screens such

as the ''yeast 2-hybrid assay'' or co-immunoprecipitations. This work, and descriptions of the likely biological functions of many of these proteins, has been reviewed recently by Thompson and Schild. A number of ongoing studies are aimed at characterizing the functional consequences of these interactions and providing some molecular detail regarding specific protein domains and residues involved in these interactions. Briefly, one of the best-characterized interactions is between yeast Rad51 and Rad52 proteins. This work led to the identification of Rad52 as a ''mediator'' of Rad51 function, that is, Rad52 assists with formation of Rad51 filaments at the site of a DNA double-strand break, and also helps Rad51 compete with other DNA binding proteins that may block its function. This particular aspect of Rad52 function is particularly interesting because it appears to have been conserved in all organisms that perform RecA/Rad51-mediated HR. For example, RecFOR assists RecA in a way similar to the Rad52/Rad51 interaction, and, in human cells, the BRCA2 protein displays a ''mediator'' function regarding its role in regulating assembly of Rad51 nucleoprotein filaments.

Important questions remain regarding how the mechanistic differences seen for bacterial RecA and eukaryotic RadA/Rad51 proteins relate to the various mediators and other proteins that assist each recombinase, as well as varied cellular environments in which these proteins catalyze recombination events.

7 Future Directions

Homologous recombination is one of several major DNA repair pathways dedicated to preserving the integrity of genetic information and is found in all free living organisms. This pathway operates to repair errors that occur frequently during normal metabolic processes such as DNA replication, as well as more catastrophic DNA lesions resulting from exposure to environmental mutagens. In eukaryotic organisms, recombination also plays an important role in proper alignment and segregation of chromosomes during meiotic division. Recent studies show that defects in homologous recombination correlate with the occurrence of several cancer syndromes in humans, thus emphasizing the need for a more detailed mechanistic understanding of recombination proteins. Studies over the past several years have significantly improved our understanding of the molecular design of the bacterial RecA protein and how its many structural domains coordinate their functions to carry out a wide variety of activities that are mechanistically unrelated, such as regulation of gene expression, catalysis of DNA strand exchange, and promotion of DNA synthesis by error-prone polymerases. RecA is a classical allosterically regulated enzyme, and ATP binding triggers a number of conformational changes that activate the protein for its diverse functions. Recent insights from new modeling procedures as well as new structures of archaeal and eukaryotic RecA-like proteins (RadA and Rad51, respectively) have significantly improved our understanding of the catalytic organization of RecA. RecA-like proteins in higher organisms must catalyze the same DNA strand exchange reaction as in bacteria, but the greater complexity of the cellular environment as well as the DNA substrate itself (chromatin) demands a more sophisticated interplay between Rad51 and various other proteins

involved directly or indirectly in catalyzing homologous recombination. A major challenge that is currently driving many studies in this area is to fully understand the complexities of homologous recombination in higher organisms, not only with regard to the function of Rad51 and its associated proteins but also to further our understanding of how the cell coordinates various pathways involved in the detection of DNA damage, slowing of cell growth to facilitate DNA repair, and the activation of DNA repair pathways.

Acknowledgments

The authors wish to acknowledge Dr. Martin Marinus, Dr. Nick Rhind, and Dr. Phoebe Rice for their commentary on the manuscript. Thanks to Dr. Phoebe Rice and Dr. Bill Royer for aid in making structural images. This work was supported by NIH grants GM44772 and GM65851 to K.L.K.

Keywords

Agonists
Compounds that bind to and activate receptors and include endogenous ligAnds such as hormones and neurotransmitters, chemically synthesized compounds, and natural products like alkaloids.

Antagonists
Compounds that bind to but do not activate receptors, and hence inhibit the action of agonists.

Cytokines and Growth Factors
Proteins that influence proliferation, differentiation, maturation, and survival of cells. Cytokines include interleukins (IL), which are produced by leukocytes and control leukocyte function, and interferons (IFL) which are produced in response to virus infection. Growth factors are produced constitutively and act on nonhematopoietic cells, whereas cytokines are produced transiently and are mostly involved in hematopoiesis and immune or inflammatory responses. In a broader sense, cytokines include growth factors.

GRKs (G Protein–Coupled Receptor Kinases)
Protein serine/threonine kinases that phosphorylate activated forms of GPCRs (e.g. agonist-bound GPCRs and light-activated rhodopsin) specifically.

GTP-binding Regulatory Proteins (G-Proteins or Heterotrimeric G-Proteins)
Proteins that are activated by hormone- or neurotransmitter-bound receptors and activates effectors such as adenylate cyclase, phospholipase C, and ion channels. G-proteins are composed of an α-subunit with GTP-binding activity and $\beta\gamma$ subunits.

Hormones
Chemical substances that are released from one cell and modulate the function of other cells, which are usually located in remote organs.

MAP Kinase (MAPK)
Mitogen-activated protein kinase, a serine/threonine kinase in the signal transduction pathway that is triggered by activation of growth-factor receptors. Extracellular signal-regulated kinase (ERK) is another name. MAP kinase kinase (MAPKK or MEK (MAPK/ERK kinase)) phosphorylates both tyrosine and threonine residues in MAP kinase and activate MAP kinase. MAPKK kinase (MAP kinase kinase kinase, MAPKKK, or MEK kinase) phosphorylates serine residues in MAPKK and activates MAPKK.

Neurotransmitters or Transmitters
Chemical substances that are released from presynaptic terminals of an excited neuron and regulate the excitability of postsynaptic membranes of the other neuron.

Protein Serine/Threonine Kinases
Enzymes that phosphorylate serine or threonine residues in proteins, and include second messenger-activated protein kinases, such as cAMP-dependent protein kinase, protein kinase C, or Ca^{2+}/calmodulin-dependent protein kinase, and protein kinases in the signal transduction pathways such as MAP kinase.

Protein Tyrosine Kinases
Enzymes that phosphorylate tyrosine residues in proteins. Some tyrosine kinases are receptors for growth factors and are activated by binding of growth factors, whereas others are not receptors and are activated by cytokine receptors or other factors.

RGS Proteins (Regulator of G Protein–Signaling)
Proteins that accelerate GTPase activity of G-protein α-subunits and then terminate G-protein signaling.

Second Messengers
Compounds that are formed in the cells in response to the stimulation by hormones or neurotransmitters on the surface of cells (e.g. cyclic AMP, cyclic GMP, diacylglycerol, and inositol triphosphate).

SH2 Domains
The src homology domain 2 that is present in many proteins in the signal transduction pathways and interacts with domains containing phosphorylated tyrosine residues in growth-factor receptors or other proteins. A product of the src gene (sarcoma gene), src protein, contains an SH2, an SH3 (another src homology domain present in many other proteins), and a tyrosine kinase catalytic site.

Communications between cells are performed by cell–cell contact or by chemical substances like neurotransmitters, hormones, cytokines, or growth factors. These chemical substances are secreted by a cell and recognized by receptors in target cells. The binding of these ligands to their receptors initiates a series of chemical reactions. Some hormones such as steroids and thyroxin pass through cell membranes and interact with their receptors inside the cell. Most other hormones and all known neurotransmitters, cytokines, and growth factors cannot penetrate cell membranes and bind to their receptors, which are transmembrane glycoproteins, on the surface of cells. Membrane-bound receptors are classified into three major groups, ion channel-coupled receptors (ICCR), G protein–coupled receptors (GPCR), and protein kinase-coupled receptors (PKCR). In this section, we describe the molecular properties of membrane-bound receptors and intracellular signals triggered by activation of these receptors.

1 Classification of Receptors

Receptors have been named and classified by their endogenous ligands and subclassified by specific agonists and antagonists since the introduction of the receptor concept in the early 1900s by Langley. Molecular entities of receptors have been identified in the last quarter-century, which enables us to classify receptors on the basis of their structure and function. For example, receptors for acetylcholine have been classified into two types, nicotinic acetylcholine receptors and muscarinic acetylcholine receptors, on the basis of their interactions with specific agonists, nicotine and muscarine, respectively. Nicotinic and muscarinic acetylcholine receptors are further characterized by their interaction with specific antagonists, tubocurarine and atropine, respectively. It has been shown by means of purification of nicotinic and muscarinic receptors and their functional reconstitution into artificial membranes that these two receptors have completely distinct structural and functional characteristics, and that nicotinic and muscarinic receptors are, respectively, acetylcholine-gated ion channels and activators of G-proteins.

Cloning of complementary DNAs (cDNAs) encoding receptor proteins and deduction of their amino acid sequences have revealed that a number of receptors have structural and functional characteristics similar to the nicotinic receptor, constituting a superfamily of ion channel-coupled receptors (ICCRs), and a greater number of receptors have structural and functional similarity to the muscarinic receptor, constituting a superfamily of G protein–coupled receptors (GPCRs). Endogenous ligands for ICCRs are restricted to a small number of neurotransmitters. In contrast, endogenous ligands for GPCRs include almost all kinds of neurotransmitters, various hormones, autacoids, chemotactants, pheromones, and external stimulants (e.g. odorants, taste substances, and light). The structural characteristics common to all members of the two superfamilies are several hydrophobic regions, which are assumed to be transmembrane segments: GPCRs have seven such regions, and each subunit of ICCRs

has two to four. Thus, GPCRs are also referred to as seven transmembrane receptors or serpentine receptors.

Several groups of receptors for cytokines and growth factors, on the other hand, are characterized by a single transmembrane segment per subunit. Some receptors with a single transmembrane segment are tyrosine kinases with the catalytic activity to phosphorylate tyrosine residues in the receptors themselves and/or related proteins, and others do not have enzyme activity but function as activators of related tyrosine kinases. Members of another group of receptors with a single transmembrane segment have serine/threonine kinase activity. Thus, these receptors with the single transmembrane segment are somehow coupled with protein kinases and are referred to here as protein kinase–coupled receptors (PKCRs).

Table 1 summarizes the characteristics of the three major groups of membrane receptors, ICCR, GPCR, and PKCR. ICCR, GPCR, and PKCR, respectively, can be discriminated from each other by endogenous ligands (neurotransmitters, hormones/neurotransmitters, cytokines/growth factors), coupled function (ion channels, G-protein activators, protein kinases/protein kinase activators), and by the order of response rates (milliseconds, seconds, hours).

Cloning of cDNAs encoding receptor proteins and determination of the human genome sequence has revealed that multiple kinds of receptors or receptor subtypes exist for a given endogenous ligand including most neurotransmitters, hormones, and cytokines. Furthermore, a number of putative receptors are called *orphan receptors* because their cDNAs or genes have been identified on the basis of their sequence homology to those of known receptors but their endogenous ligands remain unidentified. An extreme case is the odorant receptors: approximately five hundred human receptors are believed to exist but their ligands remain to be identified except for a few receptors. One of the future challenges will be to develop specific ligands for a given receptor with a known amino acid sequence.

2 Ion Channel-Coupled Receptors (ICCR)

Endogenous ligands for ICCRs are limited to several neurotransmitters, which are acetylcholine, glutamate (and possibly aspartate), γ-aminobutyric acid (GABA), glycine, serotonin (or 5-hydroxytryptamine, 5HT), and ATP (adenosine triphosphate). ICCRs are not known for catecholamines like adrenaline and dopamine, or for peptides.

ICCRs are oligomers composed of heterogeneous subunits, although some might be homooligomers. They incorporate ion-channel function in the oligomeric structure with a transmitter-gated pore in the center of the oligomers. Receptors for acetylcholine, glutamate, serotonin, and ATP are cation channels, which are permeable to both Na^+ and K^+ (and Ca^{2+} in some cases), and receptors for GABA and glycine are anion (chloride ion) channels. Neurotransmitters are released from the presynaptic terminal and bind to ICCRs in the postsynaptic membranes. The binding leads to the opening of ion channels, followed by depolarization and excitation of the postsynaptic membranes in the case of cation channels and by hyperpolarization and inhibition of excitation in the case of anion channels. In other words, the excitatory postsynaptic potential (EPSP) and inhibitory postsynaptic potential (IPSP)

Tab. 1 Characteristics of three major groups of membrane receptors.

	Ion channel-coupled receptors (ICCR)	***G protein-coupled receptors (GPCR)***	***Protein kinase-coupled receptors (PKCR)***
Endogenous ligands	Some neurotransmitters	Neurotransmitters, hormones, autacoids, and external stimulants (odorants, taste substances, and light)	Cytokines, including growth factors, neurotrophins, and TGF-β
Structure and number of transmembrane (TM) segments	Oligomers with a pore in the center Two to four TM segments per subunit	Monomers and some dimers Seven TM segments	Dimers or oligomers Single TM segment per subunit
Immediate function of receptors induced by agonist binding	Permeation of cations or anions through pores causing depolarization or hyperpolarization of membranes	Activation of G-proteins by facilitating GTP–GDP exchange; activation of G protein-coupled receptor kinases (GRKs)	Phosphorylation of tyrosine or serine/threonine residues in receptors or activation of tyrosine kinases
Cellular responses induced by activation of receptors	Excitation of neurons and other excitable cells or inhibition of excitation	Changes in excitability of neurons or other cells: regulation of protein function and gene expression	Regulation of gene expression, cell proliferation, and differentiation
Timescale of responses	Milliseconds	Seconds	Hours

are caused by opening of transmitter-gated cation and anion channels, respectively. The time course of these responses is rapid (within the order of milliseconds). Thus, ICCRs are specified for the purpose of rapid communication in the nervous system. This does not necessarily mean, however, that the role of ICCRs is restricted to the production of EPSP and IPSP. ICCRs may also take part in the stimulation or inhibition of neurotransmitter release through presynaptic receptors, in the long-term facilitation or depression of EPSP through a subtype of glutamate receptor (NMDA receptor), or in the action on glial cells.

2.1 Nicotinic Acetylcholine Receptors

The nicotinic acetylcholine receptor is the most extensively studied and best characterized among all the receptors. Abundant nicotinic receptors are present in the electric organs of the electric eel or *torpedo*, which are homologous to skeletal muscles. Nicotinic receptors were purified from the electric organs of *torpedo* by taking advantage of their abundance and their specific interaction with snake venoms such as bungarotoxin. Purified nicotinic receptors were found to be pentameric glycoproteins composed of four distinct subunits ($2 \times \alpha$, β, γ, δ) and to show acetylcholine-gated cation channel activity when reconstituted in lipid membranes. In 1982, cDNA encoding the α-subunit of nicotinic receptors in the electric organ of *torpedo* was cloned by using its partial amino acid sequence. Thereafter, cDNAs encoding each subunit of nicotinic receptors in the *torpedo* electric organ and in the calf muscle were cloned by using the sequence homology among subunits. Amino acid sequences of each subunit were deduced from corresponding nucleotide sequences of cDNAs. The finding of homology in amino acid sequences among the four subunits indicates derivation from a common ancestor.

Each subunit is composed of 437–501 amino acid residues and has four hydrophobic domains (M1–M4) with approximately 20 amino acid residues each. Extensive studies of nicotinic receptors have been carried out by using biochemical methods such as crosslinking of receptors with acetylcholine analogs or channel blockers, gene technology (e.g. mutagenesis), and physical methods (e.g. electron microscopy and electron diffraction of receptor microcrystals). Results are summarized in the following list, and an atomic model is shown in Fig. 1(A).

1. The amino-terminal portions of each subunit are located extracellularly and are bound with sugars. Two molecules of acetylcholine bind to the amino-terminal portions of the α-subunits.
2. The four hydrophobic domains (M1–M4) of each subunit form α-helices and transverse the plasma membrane forming a pore (ion channel) in the middle of 20 transmembrane segments.
3. The five M2 segments line the pore. Leucine and valine residues in the middle of the five M2 segments are conserved among all four subunits and thought to constitute the gate of the pore.
4. The binding of acetylcholine causes a small rotation of the extracellular parts of the five subunits, which triggers a conformational change in the M2 segments and moves the hydrophobic side chains away from the ion path. Thus, these hydrophobic residues function as a gate (Fig. 1(B)).

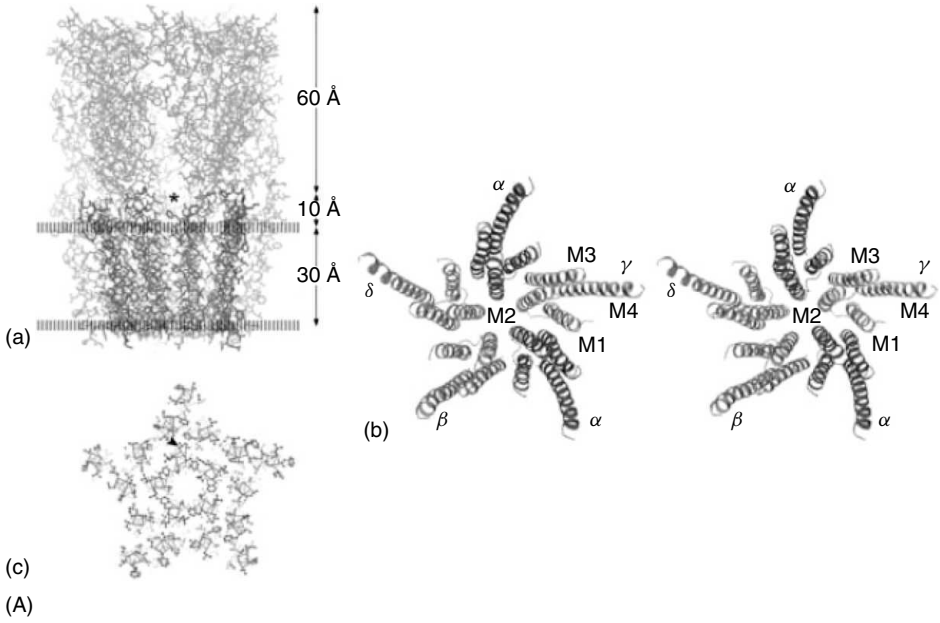

Fig. 1 Structural model of the nicotinic acetylcholine receptor (nAChR: an ion channel-coupled receptor, ICCR). (A) An atomic model with the closed pore was determined from electron images by electron cryo-microscopy of crystalline postsynaptic membranes and their reconstruction by optical diffraction and computation. The side (a) and cross-sectional (c) views show an extracellular ligand-binding domain (green), an inner, and the transmembrane segments composed of pore-facing M2 helices (blue) and lipid-facing M1, M3, M4 helices (red). (b) Stereo view of the pore, as seen from the extracellular face. (c) Cross-sectional view through the pentamer at the middle of the membrane. The pore is shaped by an inner ring of five α helices (M2), which curve radially to create a tapering path for ions, and an outer ring of 15 α-helices (M1, M3, M4), which coil around each other and shield the inner ring from the lipid layer. (B) A model for the gating mechanism. With binding of acetylcholine (ACh), two M2 α-helices of α-subunits rotate to opposite directions. This movement triggers the concerted movement of M2 α-helices of the other subunits resulting in the opening of the gate that consists of hydrophobic residues in the central part of five M2 segments. (From Miyazawa, A. et al. (2003) Structure and gating mechanism of the acetylcholine receptor pore, *Nature* **424**, 949–955) (see color plate p. xli).

5. The rate of channel opening is fast with a time constant of approximately 20 µs. The conductance of a single channel is 30 ps ($= 30 \times 10^{-12}$ A V^{-1}). This means that 2×10^4 cation molecules pass through the channel in an open time of 1 ms when the cation is derived by a potential of 100 mV: 30×10^{-12} (A V^{-1}) $\times$ 0.1 (V) $\times$ 1×10^{-3} (s) $\times$ 1/96 500 (mol C^{-1}) $\times$ 6.2×10^{23} (molecules mol^{-1}) $= 1.9 \times 10^4$ molecules.
6. The channel is permeable to both Na^+ and K^+ but not to Ca^{2+} or to anions. Anionic charges on both sides of the M2 segments contribute to the permeation of cations but not of anions.
7. In the continued presence of agonists, the channel closes with time constant of 50 to 100 ms at 20 °C (desensitization).

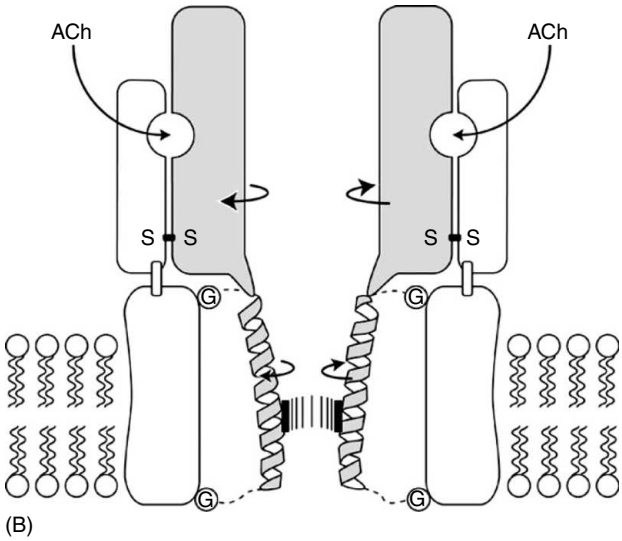

Fig. 1 (*Continued*)

Phosphorylation of nicotinic receptors by cAMP-dependent protein kinase, protein kinase C, or tyrosine kinase facilitates desensitization.

There are two kinds of nicotinic receptors in the skeletal muscle: the embryonic type ($\alpha_2\beta\gamma\delta$) and the adult type ($\alpha_2\beta\varepsilon\delta$). The denervation of skeletal muscle induces the expression of the γ-subunit and decreases the expression of the ε-subunit, which results in the conversion from the adult type to the embryonic type. The embryonic-type receptor is distributed widely in the whole area of skeletal muscle membranes, whereas the adult-type receptor is localized in the postsynaptic membranes. This specific distribution is regulated by distinct expression of *nAChR* genes in the nucleus adjacent to the synapse.

Different kinds of nicotinic receptor subtypes are present in the autonomous ganglia and the brain. Seven kinds of α-subunits (α_2–α_9, no α_8 in human), which are homologous to the skeletal α-subunit (α_1), and three kinds of β-subunits (β_2–β_4) have been identified (see Table 2). Functional receptors are thought to be pentamers like $(\alpha_4)_2(\beta_3)_3$. The effect of bungarotoxin on brain nicotinic receptors is weak or absent, except that α_7 and α_9 bind the toxin. Some brain nicotinic receptors are present in presynaptic membranes and regulate the release of glutamate. Ca^{2+} is reported to permeate through the α_7 homooligomer, while Ca^{2+} does not permeate through other nicotinic receptors including the skeletal muscle type.

2.2 Glutamate Receptors

Glutamate receptors are classified into ionotropic receptors (ion channel-coupled receptors, ICCRs) and metabotropic receptors (G protein–coupled receptors, GPCRs). Ionotropic receptors are divided by the use of a specific agonist, N-methyl D-aspartic acid (NMDA), into NMDA and non-NMDA types. Non-NMDA types are

Receptors are classified by their neurotransmitters and types, which are written in **bold** face. Most commonly used names are listed for receptors and receptor subunits. Genes for receptor subunits are expressed by names approved by the gene nomenclature committee in HUGO (Human Genome Organization). Gene loci are mapped on chromosomes of the human genome.

further subdivided into AMPA (α-amino-3-hydroxy-5-methyl-4-isoxalone propionic acid) and kainic acid (KA) types, where AMPA and KA are specific agonists for the respective subtypes. A number of different genes have been identified for subunits of each glutamate receptor (seven genes for NMDA receptor subunits, four for AMPA receptors, five for KA receptors)(see Table 2). There are also two genes encoding δ-type glutamate receptors, which have significant homology to other ionotropic glutamate receptors but whose functions remain to be identified. Some of the genes encoding glutamate receptor subunits are reported to have splicing variants: for example, eight kinds of polypeptides derived from the NMDA receptor 1 (*NMDAR1*) gene are expressed in the brain. Each glutamate receptor is believed to be a heterotetramer composed of the same type of receptor subunits.

The molecular properties of glutamate receptors are not as well understood as those of the nicotinic receptors, although the fundamental properties are assumed to be similar. Each subunit of AMPA, KA, and NMDA receptors has four hydrophobic domains (M1–M4), like the nicotinic receptors and other ICCRs, and there are some similarities in these domains between glutamate receptors and other ICCRs. Each glutamate receptor subunit, however, is thought to have three, rather than four, transmembrane domains, where M1, M3, and M4 but not M2 are the transmembrane segments. In addition, glutamate receptors are thought to be composed of four, but not five, subunits in contrast with nicotinic receptors. Thus, the extracellular part of glutamate receptors is thought to be composed of four amino-terminal parts and four loops between the M3 and M4 transmembrane segments, and to constitute the glutamate-binding site. Actually the protein complex corresponding to the extracellular domains of an AMPA receptor has been expressed, purified, crystallized, and used for X-ray analysis. The X-ray analysis showed an atomic structure composed of two domains with a clam-shaped structure and with a glutamate-binding site in the cleft of the clam shell. Four clams with eight halves of shells are assembled, and the binding of multiple glutamate molecules is supposed to cause a conformational change so as to close the shells, which should be somehow transmitted to the transmembrane domains. Recently, an atomic structure of the extracellular domain of an NMDA receptor subunit, NR1, was determined and shown to be clam shaped, as seen with the AMPA receptor. NMDA receptors have to bind both glutamate and glycine (or D-serine) to be activated, where the NR1 subunit binds to glycine (or D-serine) and the NR2 subunit to glutamate. The cleft of the clamshells in NR1 was shown to be open in the presence of antagonist, and closed in the presence of glycine or D-serine.

The M2 segment is thought to be inserted into the membrane from the intracellular side forming a loop. A certain amino acid residue in the M2 segment is critical for the selectivity of permeable ions. The genetic code for the amino acid is asparagine for NMDA receptors and glutamine for AMPA receptors. This site, however, is converted to arginine by RNA editing for the GluR2 subunit of AMPA receptors. NMDA receptors are permeable to Na^+, K^+, and Ca^{2+} ions. AMPA receptors comprised of the subunits with glutamine in this site are permeable to Na^+, K^+, and also Ca^{2+} ions with inwardly rectified voltage dependency in the current. On the other hand, AMPA receptors including the edited GluR2 subunit with the arginine residue are not permeable to Ca^{2+}

ions, and are permeable only to Na^+ and K^+ ions with linear voltage dependency in the current. The ratio between edited and nonedited GluR2 mRNA increases after birth, and almost 100% of GluR2 mRNA is edited in the adult brain.

Non-NMDA glutamate receptors play a major role in the excitatory synaptic transmission in the central nervous system. NMDA receptors are different from non-NMDA receptors in that NMDA receptors are usually not active, as the ion permeability of NMDA receptors is inhibited by Mg^{2+} ions. The inhibitory effect of Mg^{2+} is suppressed by depolarization. The NMDA receptor channel opening is also regulated by glycine or D-serine. Thus, the NMDA receptor opens only when both glutamate and glycine (or D-serine) are present and the cell membrane containing NMDA receptors has been depolarized.

Phenomena referred to as long-term potentiation (LTP) and long-term depression (LTD) have been studied in detail, particularly in the hippocampus, and are considered to represent cellular models for memory formation. LTP is defined as a sustained increase in the efficiency of synaptic transmission, and is caused by brief trains of high-frequency stimulation (e.g. 30–100 stimuli/s with duration of 5–10 s, that is, consecutive 150–1000 stimuli). On the other hand, LTD is defined as a sustained decrease in the efficiency of synaptic transmission, and is caused by low-frequency stimulation (1–3 stimuli/s with duration of 5–15 min, that is, consecutive 300–1000 stimuli). NMDA receptors are involved in both LTP and LTD in the hippocampal CA1 area. High-frequency stimuli induce depolarization of postsynaptic neurons through the AMPA receptor, which is followed by opening of NMDA receptors, Ca^{2+} entry, and activation of Ca^{2+}-calmodulin-dependent protein kinase II (CaMKII). Autophosphorylation of CaMKII makes it constitutively active, and the persistent active form of CaMKII binds to the NMDA receptor NR2B subunit in postsynaptic membranes. High-frequency stimulation causes the translocation of the AMPA receptor containing the GluR1 subunit from intracellular organelles into synaptic membranes, which results in increases of the excitatory postsynaptic current. CaMKII activation and AMPA receptor translocation are thought to be somehow related to the formation of LTP. On the other hand, low-frequency stimuli induce mild activation of NMDA receptors followed by low-level elevation of Ca^{2+} concentrations, which causes the activation of protein phosphatases. Phosphatase activity induces the internalization of AMPA receptors into intracellular vesicle pools, which decreases the excitatory postsynaptic current. Thus, LTP and LTD, which are measured as the increase and decrease in the excitatory postsynaptic current, respectively, are linked with recruiting and internalization of the AMPA receptor on the synaptic surface and also with the activation of CaMKII and phosphatases, but the exact molecular mechanisms are yet to be identified.

Glutamate receptors are highly enriched in postsynaptic membranes and are anchored by so-called scaffolding proteins. Excitatory synapses in the central nervous system are characterized by the electron dense regions in postsynaptic sites, which are known as postsynaptic density (PSD). One major component in postsynaptic densities is PSD-95, which binds to NMDA receptor NR2 subunits and some voltage-gated potassium channels. The carboxy termini of the latter proteins have the consensus sequence of Thr/Ser-X-Val (X is any amino acid residue), to which the

so-called PDZ domain in PSD-95 binds. As there are three PDZ domains in a single PSD-95 molecule, coexpression of PSD-95 with NMDA receptors in cultured cells induces their clustering. Proteins referred to as GRIP (glutamate receptor interacting protein) also have PDZ domains and bind to AMPA receptors. These molecules function as scaffolding proteins contributing to assembling receptors, ion channels, and enzymes in postsynaptic sites. These molecules bind directly or indirectly to motor proteins of the kinesin family, which are supposed to transport receptor molecules from the cell body to the dendrite.

2.3 $GABA_A$ Receptors

There are two kinds of GABA receptors, $GABA_A$ and $GABA_B$, which are ion channel-coupled receptors (ICCR) and G protein–coupled receptors (GPCR), respectively. Eighteen kinds of $GABA_A$ receptor subunits have been identified in the human genome (six α, three β, three γ, one ε, one δ, one π, one θ, two ρ). Various oligomers with different combinations of these subunits are thought to exist *in situ*. The fundamental structure of $GABA_A$ receptors is thought to be similar to that of nicotinic receptors, that is, a pentamer of subunits with four transmembrane segments. $GABA_A$ receptors, however, are anion channels, in contrast with nicotinic receptors, and there are more positive amino acid residues on both sides of the M2 segments of $GABA_A$ receptor subunits compared with the M2 segments of nicotinic receptors. These positive charges are considered to help attract chloride ions before their permeation through the pores. Binding of GABA to $GABA_A$ receptors and the subsequent opening of chloride channels causes the hyperpolarization of postsynaptic membranes and thereby the suppression of excitation.

$GABA_A$ receptors take a major role in the inhibitory synaptic transmission in the brain. Different kinds of drugs are known to interact with $GABA_A$ receptors. Benzodiazepines and related compounds are tranquilizers and facilitate the action of GABA by increasing the affinity of the receptor for GABA. Barbiturates, which induce sleep, also increase the action of GABA. Picrotoxin, on the other hand, blocks the channel and then acts as an inducer of seizures. The effect of drugs appears to be subtype-specific. $GABA_A$ receptors that do not contain γ-subunits are not affected by benzodiazepines. This suggests the possibility that various drugs with different subtype specificity might be developed in the future and be used for different kinds of neurological or psychiatric diseases.

2.4 Other Ion Channel-Coupled Receptors

Glycine receptors are chloride channels and play a role in the inhibitory synaptic transmission mostly in the spinal cord. There are four subunit genes in human (three α, one β). Glycine receptors are thought to have a structure similar to nicotinic receptors and $GABA_A$ receptors.

A number of receptors for serotonin (or 5-hydroxytryptamine, 5HT) are GPCRs, and only serotonin $5HT_3$ receptors are cation channels. The $5HT_3$ receptors are expressed in forebrain, hippocampus, brainstem, and spinal cord, although the expression is restricted to some populations of neurons. At first only one gene corresponding to $5HT_{3A}$ was identified, and the channel properties of the $5HT_{3A}$ homopentamer were found to be different from those of native

brain $5HT_3$ receptors. After homology search of the human genome sequence, another gene corresponding to $5HT_{3B}$ was found, which had significant homology to the *5HT*$_{3A}$ gene. When both $5HT_{3A}$ and $5HT_{3B}$ cDNAs were coexpressed, the expressed receptor showed channel properties similar to those of native brain receptors.

Purinergic receptors are divided into two groups, P2X receptors and P2Y receptors, which are ion channel-coupled receptors (ICCR) and G protein–coupled receptors (GPCR), respectively. There are at least seven different subunit genes for P2X receptors in the human genome. These subunits are clearly distinct from subunits of either nicotinic or glutamate receptors in that P2X subunits have only two transmembrane domains. The loop between the two transmembrane domains is located extracellularly and is assumed to be the ATP-binding domain because it has an ATP-binding motif and ATP acts on the channel from the extracellular phase. P2X receptors appear to form either homo- or heterooligomers, and some receptors are suggested to be trimers although this remains to be proven in a more direct manner. P2X receptors are ATP-gated cation channels with equal permeability to Na^+ and K^+ and a significant permeability to Ca^{2+}. P2X receptors are expressed in post- and presynaptic membranes in the central nervous system, and may contribute to ATP-driven excitatory postsynaptic current (EPSC) although the ATP-driven EPSC is relatively small and less abundant as compared with that driven by glutamate receptors. P2X3 is expressed in some sensory neurons, and is thought to serve as a pain sensor. Recently, P2X4 in microglia is reported to play an important role in evoking and maintaining a kind of neuropathic pain.

3
G Protein-Coupled Receptors (GPCR)

Endogenous ligands of GPCRs include all neurotransmitters except glycine, most hormones and autacoids, several chemotactic factors, and external stimulants such as pheromones, odorants, and taste substances. Chemically, these ligands are diverse and include amino acids, peptides, proteins, amines, nucleosides, nucleotides, lipids such as prostaglandins and leukotrienes, Ca^{2+} ion, H^+ ion, and various organic compounds acting as odorants. Rhodopsin and optic pigments, which are receptors for light, are also GPCRs (Tables 3 and 4). The number of GPCR gene species in the human genome is estimated to be 800 to 900, approximately half of which are odorant receptors. Three to four hundred GPCRs are known to have endogenous ligands, but more than one hundred GPCRs are considered to be orphan receptors for which the endogenous ligands remain to be identified.

Each GPCR was thought to be a homogeneous protein and to exist as a monomer. However, recently $GABA_B$ and metabotropic glutamate receptors (mGluRs) have been shown to exist as dimers. Some GPCRs in the rhodopsin family, which is the major group of GPCRs, are also reported to form homo- or heterooligomers with intact functions. However, it is not clear yet whether oligomerization is a prerequisite for the function of most GPCRs or whether it is required for only a small number of GPCRs.

The function of GPCRs is to activate heterotrimeric G-proteins ($\alpha_{GDP}\beta\gamma$), that is,

to stimulate the dissociation of GDP from G-proteins and thereby facilitate the binding of GTP to G-proteins followed by dissociation into α_{GTP} and $\beta\gamma$ subunits (see Fig. 2). Activated G-proteins, that is α_{GTP} and $\beta\gamma$ subunits, stimulate or inhibit enzymes that synthesize or break down second messengers such as cAMP, diacylglycerol and inositol 1,4,5 triphosphate (IP_3). Thus, the information of the presence of hormones, neurotransmitters, odorants or other molecules outside of cells is converted to changes in concentrations of second messengers, which affect activities of protein serine/threonine kinases; for example, cAMP and diacylglycerol activate cAMP-dependent protein kinase (A kinase) and protein kinase C (C kinase), respectively. In addition, IP_3 interacts with and opens the IP_3-gated Ca^{2+}-channel in intracellular vesicles causing an increase in intracellular Ca^{2+} concentrations, which may activate Ca^{2+}-calmodulin-dependent protein kinases. These protein kinases affect activities of different kinds of proteins including enzymes, ion channels, and so on. In addition, expression of some genes is regulated through these protein kinases; for example, CREB (cAMP responsive element (CRE) binding protein) is phosphorylated by cAMP-dependent protein kinase. Phosphorylated CREB, together with CREB binding protein, stimulates the transcription of genes that reside downstream of CRE with a sequence of TGACGTCA.

As for the relation between GPCR and ion channels, there are different types depending on the species of ion channels; some ion channels like the inward-rectified K^+ channel in the heart are directly regulated by G-protein $\beta\gamma$ subunits, cation channels in visual or olfactory cells are regulated by cGMP or cAMP, and many other ion channels are thought to be directly or indirectly regulated by phosphorylation by second messenger-dependent protein kinases. In any case, the time courses of their opening or closing after ligand binding to the receptor are much

Fig. 2 Structures of rhodopsin and a heterotrimeric G-protein. (A) An atomic model for rhodopsin was obtained by X-ray analysis of the rhodopsin crystal. (a) A stereoview in parallel to the plane of the membrane. The upper and lower parts of this model correspond to the intra- and extracellular domains respectively. There are seven transmembrane α-helixes (I-VII), another α-helix in the C-terminal region (VIII), 11-cis-retinal (yellow) in the transmembrane region, and two β-sheets (1–2 and 3–4) and sugars in the N-terminal region. View of the receptor from the cytoplasmic (b) and intradiscal (extracellular) side (c) of the membrane. (From Palczewski, K. et al. (2000) Crystal structure of rhodopsin: A G protein-coupled receptor, *Science* **289**, 739–745). (B) Receptor-G protein interaction. (a) A structural model for the cytoplasmic surface of the M_1 muscarinic receptor. Residues important for interaction with G protein are shown in red, magenta (i3 loop), and yellow. The arrows indicates the outward movement of TMb and increased mobility of TM7 and helix 8, which are thought to accompany receptor activation. (b) A structural model for the interaction between G protein-coupled receptor (GPCR) and G-protein $\alpha\beta\gamma$ trimer. Structures are taken from crystal structures of rhodopsin and a chimera of transducin (Gt) and Gi. The N- and C-termini of the transducin α-subunit and the α4-β6 loop sequences, which are thought to be involved in the interaction with GPCR, are shown in red. The switch-II helix in the G-protein α-subunit is bound to the β-subunit when the α-subunit is bound to GDP, and is subject to conformational change and is released from the β-subunit when the α-subunit is bound with GTP. (From Lu, Z.L. et al. (2002) Seven-transmembrane receptors: crystals clarify, *Trends Pharmacol. Sci.* **23**, 140–146) (see color plate p. xlii).

slower (10 ms–1 min) as compared to IC-CRs (ms).

3.1 Structure, Function, and Species of GPCRs

The amino-terminal domain of GPCRs is considered to be located extracellularly, and the carboxy-terminal tail in the cytoplasm. This assumption is consistent with the facts that the consensus sequence for attachment of sugars (Asn-X-Ser/Thr) is present in the amino-terminal tail for almost all members of this family and that phosphorylation sites are in the carboxy-terminal tail for some GPCRs. The amino and carboxy-terminal tails have a variable length ranging from several tens to several hundreds of amino acid residues. Seven hydrophobic regions (20–25 amino acid residues each) are assumed to transverse the plasma membrane forming α-helices. The three intracellular and extracellular loops are generally short (10–30 amino acid residues) except that some receptors have a long third intracellular loop. Recently, the crystal structure of rhodopsin was determined at atomic resolution (see Fig. 2). This structure confirmed the above assumption

Opioid		μ, δ, κ, (G_i/G_o)
Tachykinin		NK1–3 (G_q)
Adenosine		A_{1-3} (G_i/G_o) $A_{2A,2B}$ (G_s)

and demonstrated that rhodopsin actually has seven transmembrane α-helices with amino- and carboxy-terminal tails in the outside and inside of the cells respectively. In addition, it was revealed that rhodopsin has an eighth α-helix between the seventh transmembrane α-helix and the palmitoylated cysteine residues in the carboxy terminus, and a disulfide bond between cysteine residues in the third transmembrane segment and in the loop between the fourth and fifth transmembrane segments.

On the basis of sequence similarities, mammalian GPCRs are divided into three major groups. Group A (rhodopsin family) is the largest one and includes rhodopsin and odorant receptors, receptors for neurotransmitters like acetylcholine and other amines, and receptors for peptides and other ligands such as nucleosides, nucleotides, and lipids. Approximately 20 amino acid residues in the transmembrane segments are highly conserved among members of this group, and most members have cysteine residue(s) at conserved

Tab. 4 G protein-coupled receptors (GPCRs) for hormones, exogenous stimulants, and other ligands except typical neurotransmitters.[a]

Chemokines	MIP1a, MCP1, IL8A,B			
Neuropeptide Y	Y1			
Light	Rhodopsin	G_{t1}	cGMP – phosphodiesterase activation	cGMP decrease
	cone pigments (blue, red, green)	G_{t2}		Hyperpolarization
Taste	20–30 species	G_g	cAMP – phosphodiesterase activation	cAMP Decrease Depolarization

Group 3				
PAF (platelet-activating factor)		G_q G_{11}	Phosphatidylinositol-specific phospholipase C β types	Increase in diacylglycerol (DG) and IP_3
Thromboxane		G_{14}		
Prostanoid	FP, TP, EP1,3	G_{15}		Activation of protein kinase C
Bombesin	B1,2			
Endothelin	ET(A), (B)			Increase of Ca^{2+}, and activation of Ca^{2+}-calmodulin kinase
Angiotensin	AT1			
Vasopressin/oxytocin	V1A,1B, OT			
Cholecystokinin/gastrin	CCK(A),(B)			
Bradykinin	BB1,2			
Group 4				
Thrombin		G_{12}	ρ GEF activation	Activation of ρ and then ρ-kinase
Thromboxan		G_{13}		Reorganization of cytoskeleton and change in cell motility

[a]GPCRs for typical neurotransmitters are shown in Table 3. It is difficult in some cases to distinguish between neurotransmitters and nonneurotransmitters (hormones, autacoids, or neuromodulators), and the distribution of some compounds between Table 3 and Table 4 is more or less arbitrary. Noradrenaline and adrenaline may be taken as both neurotransmitters and hormones, and serotonin; histamine, and adenosine are both neurotransmitters and autacoids. Somatostatin, VIP, and other peptides are known to be released from neurons and to act on neurons although they are listed in Table 4.

[b]Receptors are grouped by their G-protein coupling properties.

positions in the carboxy termini, homologous to the ones that are palmitoylated in rhodopsin. Group B (secretin receptor family) consists of receptors for rather large peptides like secretin, glucagon, and so on, and these receptors have a large amino-terminal domain with conserved disulfide bonds. Group C (glutamate receptor family) consists of metabotropic glutamate receptors (mGluR), $GABA_B$ receptors, and putative taste receptors. These receptors have large amino- and carboxy-terminal domains and short and highly conserved third intracellular loops. Cysteine residues in the extracellular loops two and three, which are known to form a disulfide bond in rhodopsin, are conserved in most GPCRs. The ligand-binding pocket is formed by transmembrane domains in the case of Group A receptors. On the other hand, Group B and C receptors contain the ligand-binding domain in the large amino-terminal segment. The glutamate-binding domain of mGluRs is homologous to the amino acid binding domain of bacterial periplasmic binding proteins.

GPCRs were believed to exist as monomers, but various lines of evidence have indicated that class C receptors form dimers and function as dimers. An atomic structure of the ligand-binding domain of the mGluR1 indicated that the ligand-binding domain consists of a homodimer, each subunit of which has two globular domains with a cleft for the ligand. In the case of the $GABA_B$ receptor, two kinds of $GABA_B$ receptors, $GABA_BR1$ and $GABA_BR2$, were shown to have a higher affinity for GABA when they were coexpressed in cultured cells than when each receptor was expressed separately, indicating the formation of a heterooligomer. Native $GABA_B$ receptors are thought to be heterooligomers because they have high affinity for GABA, and $GABA_BR1$ and $GABA_BR2$ are coimmunoprecipitated from extracts solubilized from brain membranes. Taste receptors with a long amino terminus were also shown to have a high affinity for amino acids or nucleosides when heterooligomers were formed. A number of examples were reported indicating that class A receptors also may form homo- or heterooligomers and that the formation of oligomers may affect the affinity and specificity for ligands and receptor trafficking. Oligomerization with components other than GPCRs was also reported: for example, calcitonin receptor-like receptor interacts with a protein with a single transmembrane segment called *RAMP* (receptor activity–modifying protein), and the dopamine D5 receptor interacts with the $GABA_A$ receptor. It is clear that some class A receptors may form and function as oligomers, but it remains to be clarified whether their oligomerization is a general phenomenon under physiological conditions.

The binding sites in GPCRs for G-proteins are thought to be the second and third intracellular loops and the carboxy-terminal tail. Following ligand binding, GPCRs are supposed to undergo conformational changes in the ligand-binding site at first and then, secondarily, in the G protein–binding sites. The molecular details involved in these conformational changes, however, remain to be clarified although extensive modeling studies have been carried out with the rhodopsin system.

3.2 GTP-Binding Regulatory Protein (G-Protein)

G-proteins are composed of three subunits, $\alpha\beta\gamma$, the molecular weights of which are approximately 40, 35, and 5–10 kDa,

respectively. The crystal structure of the $\alpha\beta\gamma$ trimer was determined (Fig. 2). G-proteins are not transmembrane proteins but are bound to cell membranes through prenyl groups and fatty acids attached to the carboxy terminus of the γ-subunit and the amino terminus of the α-subunit, respectively. The α-subunit has a binding site for GTP or GDP and harbors GTPase activity. The β-subunit has seven repeated domains forming a tertiary structure like a seven-bladed propeller, and the γ-subunit is tightly bound with the amino-terminal part of the β-subunit. G-proteins bound with GTP dissociate into α_{GTP} and $\beta\gamma$ subunits, and the α_{GTP} and $\beta\gamma$ subunits activate or inhibit effectors. The activity of the α_{GTP} and $\beta\gamma$ subunits is terminated by hydrolysis of GTP and the subsequent formation of $\alpha_{GDP}\beta\gamma$ trimer. The $\alpha_{GDP}\beta\gamma$ trimer is converted into the α_{GTP} and $\beta\gamma$ subunits by action of the agonist-bound receptor. The agonist-bound receptor (aR) facilitates release of GDP from G-proteins and forms a complex with guanine nucleotide-free G-proteins (aRG complex), as evidenced by reconstituting purified receptors and G-proteins in artificial membranes. The aRG complex is thought to be formed as a transient intermediate *in vivo*, forming the transition state. The activation energy of the reaction path $G_{GDP}-G-G_{GTP}$ is considered to be reduced by taking the route of $G_{GDP}-aRG-G_{GTP}$, as is the case for the formation of enzyme–substrate complexes. Actually, aR activates multiple G-proteins like a catalyst.

Seventeen different α-subunit genes have been identified, and they are classified into four groups according to the homology of their amino acid sequences: G_s, G_i/G_o, G_q, and G_{12} (see Table 3). Multiple species of β (5) and γ (11) subunits have been identified, although their functional differences remain to be clarified. Several kinds of $\beta\gamma$ subunits are shown to interact equally well with both G_s-α and G_i-α, and several combinations of β- and γ-subunits have been expressed in cultured cells and shown to form a complex with each other and with G_i-α subunits. The specificity of interaction of the three subunits, however, has not been fully elucidated.

G_s-α (or α_s) that is bound with GTP activates adenylate cyclase. G_{olf}-α is an olfactory bulb-specific α-subunit and activates adenylate cyclase as G_s-α does. At least nine different adenylate cyclases have been cloned and all of them are activated by G_s-α. The addition of $\beta\gamma$ subunits in the presence of G_s-α further stimulates adenylate cyclase II but inhibits adenylate cyclase I. The $\beta\gamma$ subunit alone neither stimulates nor inhibits adenylate cyclase I or II. Ca^{2+}-calmodulin further stimulates adenylate cyclase I in the presence of G_s-α, whereas Ca^{2+} inhibits adenylate cyclase V and VI. These synergistic mechanisms of stimulation or inhibition may be utilized for detection of coincident stimulation of a single neuron by one receptor linked to G_s and the other receptor linked to elevation of $\beta\gamma$ subunits or Ca^{2+}.

Most α-subunits in the second group of G-proteins (G_{i1}-α, G_{i2}-α, G_{i3}-α, G_o-α, G_{t1}-α, G_{t2}-α, and G_g-α) are ADP-ribosylated by pertussis toxin. G-proteins in the other groups and G_z in this group are not ADP-ribosylated by pertussis toxin. The ADP-ribosylated G-proteins lose the ability to interact with receptors, and hence the inhibition by pertussis toxin of receptor-mediated reactions indicates the involvement of these G-proteins. G_i-α and G_z-α inhibit adenylate cyclase I, V, and VI, and G_o-α inhibits adenylate cyclase I. The amounts of G-proteins present in the mammalian brain show the following order: $G_o > G_{i1} > G_{i2}, G_s >$

G_q. This indicates that the major source of G-protein $\beta\gamma$ subunits in the brain is from members of this second group. Thus, activation of G-proteins in this group causes the stimulation of adenylate cyclase II through $\beta\gamma$ subunits and inhibition of adenylate cyclase I through both α- and $\beta\gamma$ subunits. In addition, the $\beta\gamma$ subunit directly interacts with and opens an inward-rectified K^+ channel (GIRK or Kir3). The K^+ channel in the heart is regulated by acetylcholine released from the vagus nerve through muscarinic M_2 receptors and G_i, probably G_{i2}. Similar inward-rectified K^+ channels are known to be present in the brain. A certain kind of voltage-gated Ca^{2+} channel is known to be closed by G-proteins belonging to this group through direct interaction between channels and G-protein α-subunits.

G_t (or transducin) is a retina-specific G-protein, and G_{t1}-α and G_{t2}-α are present in rod and cone cells, respectively. G_{t1} and G_{t2} are activated by light-absorbed rhodopsin and cone pigments, respectively. G_t-α bound with GTP activates cGMP-phosphodiesterase resulting in a decrease of cGMP concentrations. As cGMP interacts with and opens cation channels and depolarizes visual cells, light stimulation causes hyperpolarization of visual cells. G_g (or gustducin) is a taste bud–specific and transducin-like G-protein, and is activated by receptors for taste substances and activates cAMP phosphodiesterase.

G_q-α and related α-subunits (α_{11}, α_{14}, α_{15} (or α_{16})) activate phosphatidylinositol-specific phospholipase C β types (PLCβ), which catalyze the formation of inositol 1,4,5 triphosphate (IP_3) and diacylglycerol (DG) from phosphatidyl inositol 4,5-bisphosphate. The GTPase activity of G_q-α, G_{11}-α, or G_{14}-α is stimulated by PLCβ, which shortens the lifetime of the active α_{GTP} forms. There are several species of PLCβ; PLCβ2 and PLCβ3 are stimulated by G-protein $\beta\gamma$ subunits, whereas PLCβ1 is either inhibited or stimulated by $\beta\gamma$ subunits. Stimulatory effects of $\beta\gamma$ subunits are observed even in the absence of G_q-α, in contrast with the fact that the stimulation by $\beta\gamma$ subunits of adenylate cyclase II requires the presence of G_s-α. Stimulation of phosphatidyl inositol turnover by G_i- or G_o-coupled receptors may be due to activation of PLCβ2 or PLCβ3 by G-protein $\beta\gamma$ subunits.

G_{12} and G_{13} constitute a different group and are present ubiquitously. Receptors for thrombin and thromboxan A2 are coupled with $G_{12/13}$, and the GTP-bound form of $G_{12/13}$-α activates ρ GEF (a guanine nucleotide exchange factor of the small GTP-binding protein ρ). The activated GTP-bound form of ρ activates ρ-kinase resulting in the rearrangement of the actin cytoskeleton. Thus, G_{12} appears to be involved in cell motility.

3.3 Classification of GPCRs and Specificity of GPCR-G Protein Interaction

GPCRs may be classified according to the homology of amino acid sequences, the kind of endogenous ligands, or the species of G-protein α-subunits with which they interact. Neurotransmitter receptors are summarized in Table 3, where GPCRs are classified by their ligands. Other GPCRs are classified by G-protein interactions and are shown in Table 4. The best-characterized receptors, which interact with G_s-, G_i/G_o-, and G_q-type G-proteins, are β-adrenergic receptors, M_2 muscarinic and α_2 adrenergic receptors, and M_1 muscarinic and α_1 adrenergic receptors, respectively. There are at least three

subtypes for each of the β, α_2, and α_1 adrenergic receptors (Table 3). Thus, adrenaline or noradrenaline may activate at least three different G-proteins through nine different receptors. The function of adrenaline (noradrenaline) on a certain cell will depend on species of receptors expressed in the cell. In the case of acetylcholine, there are five different muscarinic acetylcholine receptors; M_2 and M_4 muscarinic receptors are coupled with G_i/G_o family G-proteins, and M_1, M_3, and M_5 receptors with G_q family G-proteins.

The specificity of interaction between receptor subtypes and distinct G-proteins is different depending on receptor and G-protein species. In reconstituted systems of purified receptors and G-proteins, the M_2 muscarinic receptor interacts equally well with G_{i1}, G_{i2}, and G_o and the M_1 muscarinic receptor interacts equally well with G_q, G_{11}, G_{14}, but the M_2 receptor does not interact with G_q family G-proteins nor does the M_1 receptor couple to G_i/G_o family G-proteins. Some receptors show a stricter specificity for members of the G_i/G_o family than the M_2 receptor; the α_{2A} adrenergic and A_1 adenosine receptors show higher affinity for G_{i3} than for G_{i1}, G_{i2}, and G_o, and the D_{2L} dopamine receptor shows a higher affinity for G_{i2} than for other G_i/G_o proteins. On the other hand, some receptors including the turkey β-adrenergic and the substance P (NK1 tachykinin) receptors are known to interact with both G_s and G_q family G-proteins. Among 146 GPCRs examined, 36 (25%), 76 (52%), and 51 (35%) interact with G_s, G_i/G_o, and G_q respectively, and 14 GPCRs interact with more than two kinds of G-proteins: 1, 3, 7, and 3 interact with G_s/G_i, G_s/G_q, G_i/G_q, $G_s/G_i/G_q$, respectively (cf. The IUPHAR compendium of receptor characterization and classification, IUPHAR Media, 1998). In the interactions of muscarinic receptors and G-proteins, amino acid sequences (approximately 20 amino acids) in the N- and C-terminal portions of the third intracellular loop in muscarinic receptors are critical for determining the specificity of their interaction (M_1, M_3, M_5-G_q and M_2, M_4-G_i/G_o). On the other hand, alternatively spliced forms of prostaglandin EP_3 receptors, which have different carboxy-terminal tails with distinct amino acid sequences, interact with different G-proteins including G_i/G_o, G_s, and G_q. As for G-proteins, the last 10 amino acids of the α-subunits are reported to be most critical for determining the specificity for receptors. $G_{q/i}$-α, which is a chimera of G_q-α and the carboxy-terminal tail of G_i-α, interacts with G_i-coupled receptors as G_i-α does, and then activates PLCβ1 as G_q-α does. G_{16} belongs to the G_q family but interacts promiscuously with G_i-, G_s-, and G_q-coupled receptors. The specificity or promiscuity of $G_{q/i}$ or G_{16} is not general, since each of them does not interact with some G_i-coupled receptors.

3.4 Regulator of G-Protein Signaling (RGS) and G Protein-coupled Receptor Kinase (GRK)

Signaling from GPCRs to G-proteins is regulated by regulators of G-protein signaling (RGS) and G protein-coupled receptor kinases (GRK). RGS proteins are GTPase-activators of G-protein α-subunits and accelerate the inactivation of G-protein. GRKs are serine/threonine kinases, which phosphorylate activated forms of GPCRs specifically, and initiate the attenuation of GPCR-mediated responses, which is called *desensitization*.

At least 19 different RGS members have been identified, which are subdivided into several groups such as R4 (RGS1, 2, 4, 5, 8, 13, 16), R3 (RGS3), RGSZ (RGS17, 19, 20), R7 (RGS6, 7, 9, 11), and R12 (RGS10, 12, 14). All members have RGS domains, which are responsible for the activation of GTPase of G-protein α-subunits. The specificity for G-proteins depends on the species: for example, R4 and R3 RGS act on both G_i-α and G_q-α: RGS20 on G_z-α and RGS17, 19 on G_i-α; RGS12, 14 on G_i-α. R7 RGS proteins have a G-protein γ-subunit-like domain, besides an RGS domain, and bind to the G-protein β_5 subunit. The RGS–Gβ_5 complex acts on $G_o\alpha$. RGS9 is expressed in the retina and the RGS9–Gβ_5 complex acts on the transducin α-subunit (G_t-α). The specificity for G_t-α appears to be due to the binding of Gβ_5, because the RGS domain of RGS9 can bind to any α_{GTP} subunits of G_t, G_i, or G_q and activate their GTPase activity. RGS9 is anchored to photoreceptor membranes by the transmembrane protein R9AP. Patients with recessive mutations in the RGS9 or R9AP genes are reported to have difficulty in adapting to sudden changes in luminance levels. RGS proteins for G_s were missing until recently, but RGS-PX1 was found to stimulate the GTPase activity of α-subunit of G_s but not other G-proteins. Some RhoGEFs have an RGS-like domain, which functions as GTPase activator of α-subunits of G_{12} or G_{13}. In the case of p115-Rho-GEF, not only RGS-like domains but also other regions are required for full GTPase activation, although most other RGS proteins have essentially the same GTPase-activating activity as the RGS domain alone.

There are other subfamilies called *RGS-like proteins* containing RGS-like domains, which share significant similarities with RGS domains, although some of the RGS-like domains do not have GTPase-activating activity. RGS and RGS-like proteins have other domain(s) that interact with other proteins including GPCRs. Some RGS proteins of the R4 family directly interact with specific receptors via their amino-terminal domain. RGS1, 4, and 16 attenuate the IP_3 response mediated by M_3 muscarinic receptors in pancreatic acinar cells more effectively than that mediated by cholecystokinin receptor, whereas RGS2 attenuates both signals equally. RGS3 has several splicing variants, and the difference in their amino-terminal sequences specifies their target proteins. RGSL interacts with $\beta\gamma$ subunits suppressing their stimulating effect on PLCβ. RGS3T binds directly to adenylate cyclase inhibiting its activity, and has a nuclear localization signal, which enables it to translocate into the nucleus and induce apoptosis of the cell. PDZ-RGS3 has PDZ domains, which bind to the ephrin-B receptor and attenuate signaling through GTPase activation. One RGS12 splicing variant also has PDZ domain, which binds to the interleukin 8 (IL8) receptor and terminates the receptor signal specifically.

GPCRs such as rhodopsin, β-adrenergic, α_2 adrenergic, M_2 muscarinic, and other receptors are known to be phosphorylated by G protein–coupled receptor kinases (GRKs) in a light- or agonist-dependent manner. There are six kinds of GRKs. GRK1 is rhodopsin kinase and phosphorylates light-absorbed rhodopsin. Phosphorylated rhodopsin interacts with a protein called *arrestin*, and this interaction prevents rhodopsin from interacting with and activating G-proteins. The phosphorylation of rhodopsin by rhodopsin kinase is inhibited by a calmodulin-like protein called *s-modulin* or *recoverin* in a Ca^{2+}-dependent manner. The phosphorylation

of rhodopsin by rhodopsin kinase and its inhibition by s-modulin are thought to be linked to desensitization and light adaptation, respectively.

GRK2 and GRK3 are originally known as β-adrenergic receptor kinases or βARK1 and βARK2. There are $\beta\gamma$-binding sites in the carboxy terminus of GRK2 and GRK3 but not in other GRKs. The binding of $\beta\gamma$ subunits to GRK2 or 3 facilitates their translocation from the cytoplasm to the plasma membrane. GRK2 is synergistically stimulated by G-protein $\beta\gamma$ subunits and agonist-bound receptors, providing an explanation why GRK2 phosphorylates agonist-bound receptors specifically. The phosphorylation of β-adrenergic receptors by GRK2 causes uncoupling of β-adrenergic receptors from G-proteins through action of β-arrestin, which is a protein similar to arrestin and binds to phosphorylated receptors. The agonist-dependent phosphorylation of muscarinic receptors and other GPCRs by GRK2 and other GRKs facilitates their internalization into intracellular vesicles. GRK2 phosphorylation sites and sites responsible for receptor internalization reside in the carboxy terminus for β-adrenergic receptors and in the central part of the third intracellular loop for muscarinic receptors. Agonist-dependent internalization may occur through either dynamin-dependent or -independent processes depending on the species of receptors or receptor subtypes involved.

GRK2 and 3 have an RGS-like domain in their amino termini, which binds to G_q-α and suppresses its activity. The RGS-like domain has GTPase-activating activity at G_q-α although the activity is much less compared with other RGS proteins. Thus, signaling by G_q-coupled receptors may be attenuated by GRK2 in two parallel ways, that is, the phosphorylation of the receptor followed by uncoupling from G-protein and receptor internalization, and the suppression of G_q-α activity by GRK2 binding. The activity of some G_q-coupled receptors is attenuated by GRK2 although they are not substrates of GRK2.

3.5 Neurotransmitter Receptors: Roles of ICCRs and GPCRs

Neurotransmitters may be classified based on the type of receptors they interact with (cf. Table 3). Glutamate, acetylcholine, serotonin, and ATP constitute the first family, and there are both ICCRs with cation channels and GPCRs for these neurotransmitters. The fast excitatory synaptic transmission is mostly mediated by nicotinic acetylcholine receptors in the peripheral nervous system and by AMPA-type glutamate receptors in the central nervous system. GABA and glycine form the second group of neurotransmitters and participate in fast inhibitory synaptic transmission through their ICCRs with anion channels. The GPCRs for GABA are pharmacologically identified as $GABA_B$ receptors. $GABA_B$ receptors have characteristics similar to metabotropic glutamate receptors. Glycine is a unique neurotransmitter that does not seem to act on GPCRs. Amines like dopamine, noradrenaline, and histamine, peptides like opioids and tachykinins, and adenosine constitute the third group and only act on GPCRs. Some peptides like VIP and neuropeptide Y, which are listed in Table 4, are also released from neurons and act on GPCRs on the post- or presynaptic membranes. In that sense, these substances could be considered neurotransmitters, although they are usually not classified as typical neurotransmitters.

ICCRs are specified for rapid information transfer in the nervous system. GPCRs, on the other hand, are present ubiquitously in all tissues and in different species from yeasts to human beings, and the rate of signal transduction is not so fast as observed with ICCRs (Table 1). Thus, neurotransmitters that only act on GPCRs should participate only in slow synaptic transmission. The question is raised what are the functions of GPCRs for neurotransmitters that act on both ICCRs and GPCRs. Neurotransmitters released at time zero may depolarize or hyperpolarize postsynaptic membranes through ICCRs in less than a millisecond and may also activate various events through GPCRs more than 10 to 100 ms later. The fast signal transmission mediated through activation of ICCRs by neurotransmitters cannot be affected by activation of GPCRs by the same neurotransmitters released at the same time. GPCRs can be considered monitors of synaptic activities at time zero and affect synaptic activities later; for example, modification of subsequent generation of action potentials through slow excitatory or inhibitory postsynaptic potentials in a timescale of around 100 ms, modification of subsequent release of neurotransmitters through presynaptic receptors, or modification of excitability in a longer timescale by phosphorylation of ion channels or other proteins or by modification of gene expression. It will be reasonable to assume that GPCR and subsequent signal transduction are involved in LTP and LTD as well as in learning and memory formation. Actually, various lines of experimental evidence support the idea that GPCR-mediated processes are involved in the long-term regulation of brain function.

All receptors for dopamine, noradrenaline, and orexin are GPCRs, and those for acetylcholine and serotonin are also mostly GPCRs in the brain. Neurons containing these neurotransmitters are localized in specific regions of the brainstem or basal forebrain, and send axons to many regions of the brain. These neurons are thought to regulate various general activities that do not need fast information transfer, such as emotion, sleep/wakefulness, depression/excitation, or attention.

GPCRs are also involved in the recognition of external stimuli such as light, odor, or taste, although it will take at least 10 ms or may be even 100 ms or 1 s. Speed of information transfer may be critical in some cases such as a batter who is going to hit a ball thrown at a speed of 150 km h^{-1} (= 40 m s^{-1} = 4 cm m s^{-1}) or an antelope who smells a panther dashing up at a speed of 150 km h^{-1}. The delay of 10 or 100 ms corresponds to 40 cm to 4 m of movement of a ball or a panther. It is interesting to note that GPCRs have survived as the cell sensor in spite of their slow speed and ICCR-type of sensors have not appeared in the process of evolution.

4 Protein Kinase-Coupled Receptors (PKCR)

The proteins that control the proliferation, survival, maturation, differentiation, and function of cells in specific tissues or organs are grouped together as cytokines and growth factors. Cytokines include interleukin (IL) and interferons (IFN), and in the broader definition, growth factors are also considered cytokines. Different tissues produce distinct growth factors such as epidermal growth factor (EGF), platelet-derived growth factor (PDGF), hepatocyte growth factor (HGF), nerve growth factor (NGF), and so on. Both

cytokines/growth factors and hormones are defined as molecular signals that are released from one cell and regulate the function of other cells. However, they are distinct in several respects:

1. Hormones generally act on cells in tissues remote from their tissue of origin, whereas cytokines/growth factors exert major actions within the tissues that produce them.
2. Hormones are amines, lipids, peptides, and also proteins, whereas cytokines/growth factors are proteins.
3. Receptors for most hormones, which do not penetrate cell membranes, are GPCRs, whereas receptors for cytokines/growth factors are directly or indirectly linked to activation of tyrosine kinases.
4. In general, activation of GPCRs causes metabolic changes in target cells through activation or inhibition of enzymes by protein serine/threonine phosphorylation, whereas activation of tyrosine kinases through cytokine/growth-factor receptors leads to expression of specific genes and proliferation or differentiation of target cells. However, there are cases in which gene expression and metabolic functions are regulated by hormones and cytokine/growth factors, respectively.

Insulin is a hormone in the sense of (1) but a growth factor in the sense of (3). Receptors for insulin and insulin-like growth factor (IGF-1) are tyrosine kinases. Insulin itself has an activity to stimulate proliferation of cells, and insulin-like growth factor (IGF-1) has an even stronger activity. On the other hand, the receptor for interleukin 8 is a GPCR despite "rule" (3).

Receptors for growth factors/cytokines share the following characteristics:

1. With some exceptions (e.g. the α-subunit of the insulin receptor), they have a single transmembrane segment per subunit (Fig. 3).
2. The binding of agonist (protein ligand) to the extracellular domain of receptors induces the dimerization or oligomerization of receptors.
3. Dimerization or oligomerization results in receptor activation.
4. Receptor activation is directly or indirectly linked to activation of tyrosine kinases.
5. The activation of tyrosine kinases finally leads to the activation or inhibition of cell-specific transcription factors and the expression of specific genes.

Receptors for growth factors/cytokines are divided into three subgroups according to their function (Table 5). Group 1 receptors, which include receptors for growth factors like insulin, EGF, PDGF, FGF, and neurotrophins have a catalytic domain of tyrosine kinase in their intracellular domain. Group 2 receptors, which include receptors for most cytokines except growth factors and transforming growth-factor β (TGFβ), do not have catalytic domains but interact with and activate tyrosine kinases. Group 3 receptors, which include receptors for TGFβ, have a catalytic domain of serine/threonine kinase in their intracellular domain.

4.1 Growth Factor Receptors with Tyrosine Kinase Activity

4.1.1 Growth Factor Receptors

Receptors for insulin, IGF-1 and HGF are composed of two subunits, α and β. After removal of the precursor signal peptide, the insulin and HGF receptors (c-met protooncogene) are posttranslationally cleaved into two chains (α and β) that

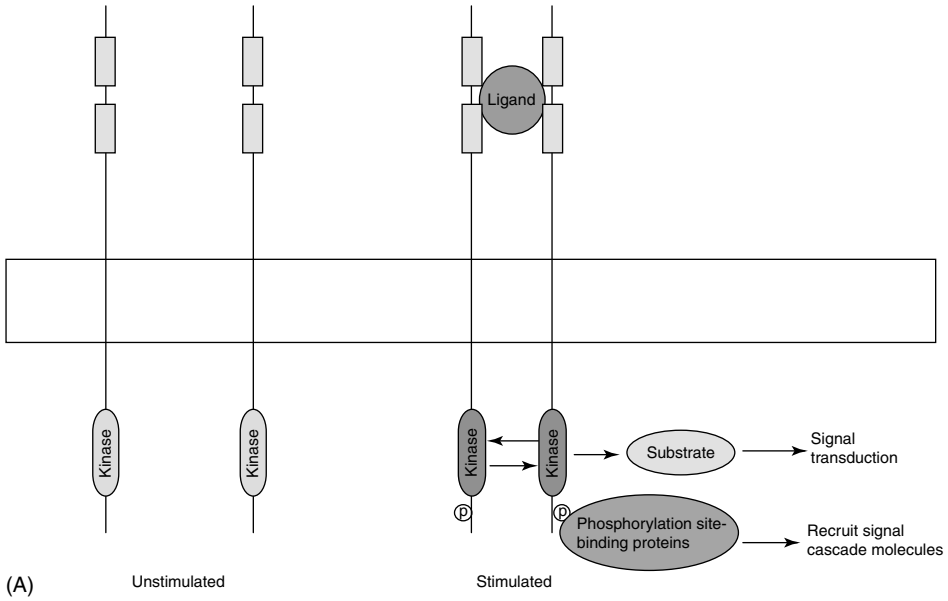

Fig. 3 Interaction of growth factors and growth-factor receptors. (A) A general model for the growth-factor receptor and other PKCRs with a single transmembrane segment. Following ligand binding, most receptors of this family form dimers (or trimers or tetramers in some cases). In many cases, ligands are dimers and then ligand binding automatically induces the oligomerization of receptors, as shown here. Dimerization of receptors triggers the signal transduction cascade, starting with autophosphorylation of a receptor subtype by the other and *vice versa*, followed by binding to phosphorylated tyrosine residues of signaling molecules, which are bound by other molecules. (B) Structure of the complex of epidermal growth factor (EGF) with the extracellular domain of EGF receptor. Binding of two EGF molecules induces the direct interaction of two EGF receptor molecules without direct interaction of EGF molecules. Two EGF molecules are observed on opposite sites. This is in contrast with the model shown in A regarding the mode of dimerization, although the outcome (receptor dimerization) is the same in both cases. (a) the ribbon diagram, (b) the top view of (a), (c) a surface model corresponding to (a). (From Ogiso, H. et al. (2002) Crystal structure of the complex of human epidermal growth factor and receptor extracellular domains, *Cell* **110**, 775–787).

are covalently linked. The α-subunit is in the extracellular space and has a ligand-binding domain, whereas the β-subunit has a single transmembrane domain and a tyrosine kinase catalytic domain in the intracellular space. Receptors for insulin and IGF-1 are composed of two α- and two β-subunits, which are linked to each other by S–S bonds between the α- and β-subunits and between the two β-subunits. Thus, the receptors for insulin and IGF-1 are tetramers even in the absence of ligands. Hence, ligand binding does not induce the dimerization of receptors, in contrast with other growth-factor receptors. The binding of insulin or IGF-1 is thought to cause conformational changes in their receptors, which lead to their activation. A major substrate for tyrosine kinase of activated receptors is insulin receptor substrate (IRS). There are four kinds of IRSs in the human genome. The expression levels of these molecules differ

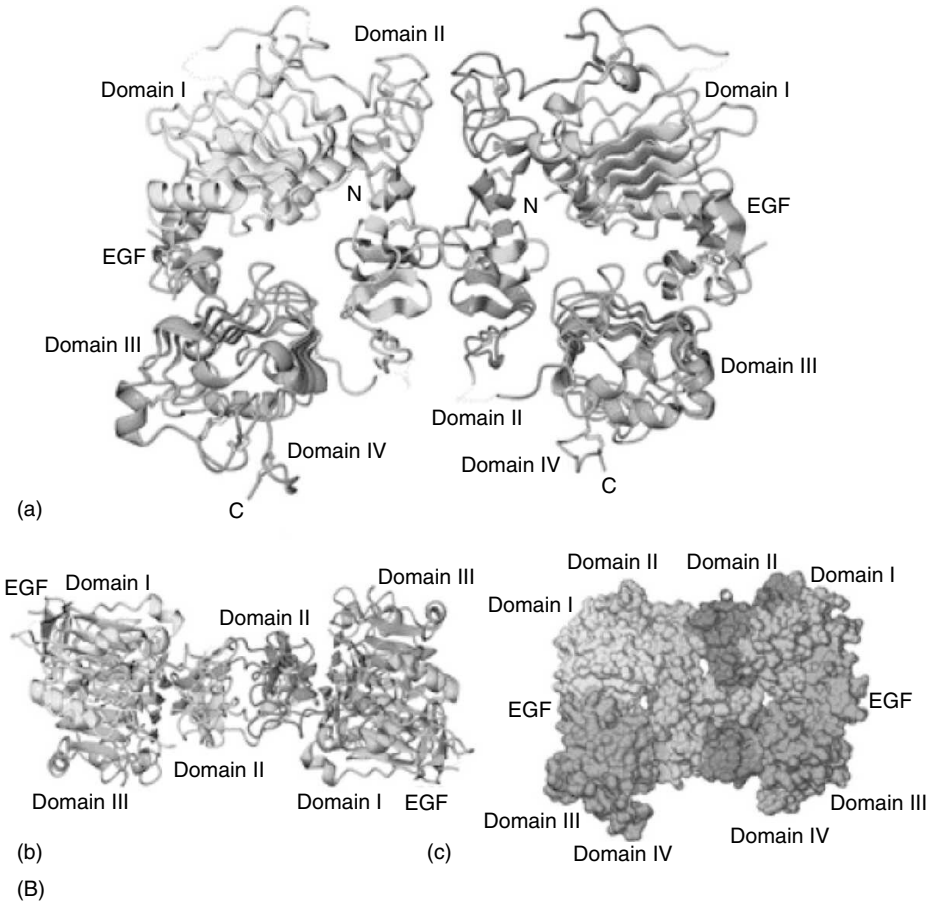

Fig. 3 (*Continued*)

from one tissue to the other, explaining the different effects of insulin in different tissues. IRS proteins have PH and PTB domains, and function as adaptor molecules. Following phosphorylation of specific tyrosine residues, IRS proteins recruit SH2 domain-containing proteins to the membrane. One of the molecules that binds to IRSs is phosphatidyl inositol 3 kinase, which is one of the key mediators in intracellular signal cascades.

Each receptor for PDGF, EGF, and FGF is a membrane protein with an extracellular ligand-binding domain, a transmembrane domain, and an intracellular tyrosine kinase domain. The molecular weights of the EGF and PDGF receptors are 120 to 130 kDa for the protein portions and 170 to 180 kDa when sugar is added. There are several characteristic domains in the extracellular part, such as cysteine-rich and immunoglobulin (Ig)-like domains. Receptors for EGF, PDGF, FGF have two cysteine-rich domains, five Ig-like domains, and two to three Ig-like domains, respectively. The cysteine-rich domains in EGF receptors and the Ig-like domains in PDGF and FGH receptors are

known to be involved in the binding of their respective growth factors.

PDGF is a dimer composed of A- and B-subunits and there are three kinds of dimers, AA, AB, and BB. There are two kinds of PDGF receptors, α- and β-receptors. The A-subunit binds only with the α-receptor, while the B-subunit binds with either α- or β-receptor. Thus, PDGF-AA induces $\alpha 2$ receptor homodimerization, PDGF-AB leads to $\alpha 2$ and $\alpha\beta$ homo- or heterodimerization, and PDGF-BB induces the dimerization of three different forms $\alpha 2$, $\beta 2$ or $\alpha\beta$. Receptor dimerization results in cross phosphorylation of tyrosine residues in one receptor subunit by the other receptor subunit and *vice versa*. Three different dimers may allow the binding of different kinds of proteins to their phosphorylated regions, which may lead to different kinds of cellular responses. Recently, other kinds of PDGF named PDGF C and D have been reported. They induce homodimers, and PDGF-CC interacts with $\alpha 2$ receptors, and PDGF-DD with $\beta 2$ (and possibly $\alpha\beta$) receptors.

EGF is a monomer, and two molecules of EGF bind to two molecules of EGF receptors (EGFR) causing formation of an EGF–EGFR–EGFR–EGF complex, where the direct interaction between two EGFRs is induced by binding of EGF but there is no direct interaction between the two EGF molecules. This is in contrast with the dimerization of NGF receptors, which is based on the direct interaction of two NGF molecules within the dimer. The EGF receptor also forms heterodimers with ErbB family receptors.

There are 23 members of the FGF family in the human genome and some of them have alternative splicing variants. There are four distinct genes for FGF receptors, *FGFR1–4*, and alternative splicing variants. These receptors form homo- and heterodimers when bound to FGFs, and intermolecular transphosphorylation occurs. FGF mediates either proliferation and/or differentiation; for example, FGF causes proliferation of NIH3T3 cells, neurite outgrowth of pheochromocytoma-derived cells (PC12 cells), and mesoderm induction in *Xenopus* oocytes. These responses appear to be mediated by a common pathway involving activation of a small GTP-binding protein, ras, but it remains unknown how these responses are differentially induced in different cells.

4.1.2 Neurotrophin Receptors

Neurotrophins are survival and differentiation factors of neurons. NGF was characterized as a survival factor for sympathetic and sensory neurons. Effects of NGF in the central nervous system are restricted to cholinergic neurons (neurons containing acetylcholine as a transmitter) in the striatum and basal forebrain. Four other neurotrophins, BDNF (brain-derived neurotrophic factor), NT-3, and NT-4/5, have been identified. All these neurotrophins are proteins with approximately 120 amino acids and form homodimers with a common three-dimensional structure.

There are two kinds of neurotrophin receptors, $p75^{NTR}$ (p75) and $p140^{Trk}$ (Trk; three subtypes TrkA, TrkB, and TrkC). Each Trk is a membrane protein with an extracellular ligand-binding domain, a transmembrane domain, and an intracellular tyrosine kinase domain. The binding of neurotrophins is thought to induce the dimerization of Trks and the autophosphorylation of dimerized receptors. p75 is also a transmembrane protein with a ligand-binding domain but does not have a tyrosine kinase domain (see Fig. 3). p75 receptors also undergo ligand-induced

dimerization. Neurotrophin-receptor complexes are internalized and transported from the axon to the soma in a retrograde fashion. The complex of phosphorylated Trk and neurotrophin activates Erk5 (a kinase of the MAP kinase family), which is followed by phosphorylation of CREB (Cyclic AMP-responsive element binding protein) and expression of specific genes for cell survival.

TrkA and TrkC specifically interact with NGF and NT-3, respectively, whereas TrkB interacts with either BDNF or NT-4/5. Expression of TrkA is localized to only a few neuronal types in the central and peripheral nervous systems, whereas both TrkB and TrkC are widely distributed throughout the brain and exist in the majority of neurons in the central nervous system, but not in nonneuronal cells such as glia. On the other hand, p75 is broadly expressed in neuronal and nonneuronal tissues. p75 is able to interact with each neurotrophin with equal affinity, but is reported to have a higher affinity for neurotrophin precursors rather than for matured neurotrophins cleaved by proteases. p75 has also been shown to bind to aggregated forms of β-amyloid and prion proteins, and to have a death domain in its intracellular region, which is somehow related to apoptotic signals.

4.1.3 Activation of the Ras-MAPK Cascade

Ligand binding to receptors results in autophosphorylation of tyrosine residues in receptors (or in IRSs in the case of insulin receptors). It is not clear and may be different among receptors if the phosphorylation of tyrosine residues further activates the catalytic activity or not. Phosphorylated tyrosine residues become targets of several proteins, which contain specific domains called SH2 (src homology domain 2). SH2 domains consist of approximately 100 amino acid residues, and recognize phosphorylated tyrosine (Y*)-containing motifs such as Y*DNV, Y*ENP, and Y*MXM. SH2 domains are included in different proteins such as nonreceptor type tyrosine kinases like src, phospholipase C γ (PLCγ), phosphatidyl inositol 3 kinase (PI3 kinase), phosphotyrosine phosphatase (PTP1C), GTPase-activating proteins (GAP), and adaptor proteins like Grb2 (growth-factor receptor bound protein 2). Amino acid sequences of various SH domains are similar but distinct from each other, and the amino acid sequences around the phosphorylated tyrosine-residue are also distinct. Thus, the interaction between SH2 domains and phosphorylated tyrosine-containing motifs is specific. For example, nine different tyrosine residues in the PDGF-β receptor are phosphorylated when activated by PDGF, and motifs containing residues 716, 771, 1009 interact with Grb2, GAP, and PTP-1D, respectively, motifs containing residues 579 and 581, 740 and 751, and 1009 and 1021 with src, PI3-kinase, and PLC-γ, respectively. Thus, a single kind of receptor may interact with and activate distinct proteins that have different kinds of SH2 domains.

A major downstream effector pathway of tyrosine kinase receptors is the MAPK (mitogen-activated protein kinase) cascade. Tyrosine kinase receptors recruit the adaptor protein Grb2. Adaptor proteins bind two different proteins and convert the binding of one protein into activation of the other protein; Grb2 has one SH2 and two SH3 domains, which are another kind of src homology domain, and binds with tyrosine kinase receptors through the SH2 domain and activates a protein called *son of sevenless* (sos) by interacting with it through SH3 domains. Sos is

a GDP–GTP exchange protein, and facilitates the release of GDP from ras, a small GTP-binding protein, and thereby facilitates the binding of GTP to ras. GTP-bound ras is the activated form of ras and interacts with and activates a serine/threonine kinase, raf kinase (or MAPKKK, MAP kinase kinase kinase). Raf kinase phosphorylates and activates MAPKK (or MEK (MAPK/ERK kinase)), which phosphorylates both tyrosine and threonine residues in MAPK (or ERK, extracellular signal-regulated kinase). Phosphorylated- and activated-MAPK is translocated into the nucleus and phosphorylates several proteins such as CREB. Finally, specific transcription factors are activated and specific genes are expressed. MAPK in PC12 chromaffine cells is activated through activation of either NGF or EGF receptors, but the final outcomes of activation of NGF and EGF receptors are opposite; activation of NGF receptors results in differentiation and arrest of proliferation, whereas activation of EGF receptors results in proliferation of PC12 cells. It seems that the duration of activation of MAPK is a critical factor and that differentiation is caused by a longer duration of MAPK activation. Activation of MAPK is also mediated through activation of other tyrosine kinase receptors including those for PDGF, insulin, and so on. There appear to be several routes from receptors to activation of ras, and also several routes for ras-mediated and ras-independent activation of MAPK.

PLC-γ binds to PDGF or FGF receptors and is translocated to membranes by interaction between phosphorylated tyrosine-containing motifs and SH2 domains, and is phosphorylated by receptors. PLC-γ is activated through translocation to membranes. Phosphorylation of PLC-γ by receptors does not affect its activity *in vitro* but is necessary to activate it in intact cells. PLC-γ catalyzes the formation of diacylglycerol and IP_3 from phosphatidylinositol 4,5-bisphosphate (PIP_2), as does PLC-β activated by the G-protein G_q. PIP_2 is known to bind to actin, α-actinin and other cytoskeletal proteins. PIP_2 bound to these proteins is not a substrate of PLC-γ but becomes a substrate of PLC-γ phosphorylated by tyrosine kinase receptors. There is a possibility that the activation of PLC-γ affects the organization of the cytoskeleton by allowing the interaction between actin and actin binding proteins through degradation of PIP_2.

PI_3 kinase catalyzes the phosphorylation of the 3′-OH of phosphatidyl inositol (PI), PI 4-phosphate, and $PI(4,5)P_2$, which results in the production of PI3-phosphate (PI3P), PI3,4-bis phosphate ($PI(3,4)P_2$), and PI3,4,5-triphosphate ($PI(3,4,5)P_3$). $PI(3,4)P_2$ and $PI(3,4,5)P_3$ bind to the Pleckstrin homology (PH) domain of intracellular signaling proteins and anchor them to cell membranes. PI3 kinase is composed of two subunits, p110 and p85, representing the catalytic subunit and an SH2-containing protein, respectively. The catalytic subunit is thought to be activated through interaction of p85 with IRSs phosphorylated by insulin receptors or with other phosphorylated proteins including receptor tyrosine kinases. Activation of PI3 kinase is necessary for insulin-mediated increase of glucose uptake, which is due to the translocation of the glucose transporter GLUT4 into cell membranes, in adipocyte, liver, and skeletal muscles. PI3 kinase increases the concentration of 3-phosphoinositide, which activates 3-phophoinositide-dependent protein kinase (PDK-1). PDK-1 phosphorylates the atypical protein kinase C and protein kinase B (PKB): PDK-1 and PKB have PH domains.

These kinases phosphorylate critical serine residues of GLUT4 resulting in its translocation to the plasma membrane. It has been suggested that PI3 kinase is involved in the regulation of cytoskeletal proteins and cell motility through activation of a subfamily of small GTP-binding proteins, rac.

4.2 Cytokine Receptors Linked with Tyrosine Kinases

4.2.1 Cytokine Receptors

Receptors for cytokines including interleukins (ILs) and interferons (IFNs) do not have tyrosine kinase activity, in contrast with receptors for growth factors. There are 30 IL genes and 25 IFN genes in the human genome. ILs are largely synthesized in lymphocytes and affect proliferation, differentiation, and functions of lymphocytes, which are involved in immune reactions. IFNs are secreted in response to virus infection, and suppress the proliferation of virus and also affect cell growth or immune responses. Receptors for ciliary neurotrophic factor (CNTF) and leukemia inhibitory factor (LIF) also lack tyrosine kinase activity, in contrast with NGF or other neurotrophin receptors. CNTF exerts potent survival effects on many peripheral neurons, in common with neurotrophins and FGF. LIF was identified also as a cholinergic differentiation factor, and has the ability to convert sympathetic adrenergic neurons into cholinergic neurons in *in vitro* experiments.

Most cytokine receptors are composed of an extracellular part, a single transmembrane domain, and an intracellular part. The extracellular parts of cytokine receptors contain cysteine-rich, Ig-like, or fibronectin type III-like domains, depending on the receptor species. The intracellular parts of the receptors do not have any known catalytic domains but have conserved motifs called *box 1 and box 2*, which are located adjacent to the transmembrane segments.

Table 5 shows some examples of cytokines and their receptors. Each of the receptors for growth hormones, erythropoietin, and prolactin is homogeneous and forms a homodimer when activated by the respective ligand. On the other hand, most cytokine receptors consist of more than two subunits, and one subunit is often shared by other cytokines. LIF, CNTF, and interleukin 6, 11 share a common receptor called gp130. LIF binds to a heteromeric complex of LIF receptor and gp130. CNTF binds to the CNTF receptor, which lacks a cytoplasmic domain, and the ligand–receptor complex then induces a heteromeric complex with the LIF receptor and gp130. Similarly, the complex of IL6 receptor with IL6 induces a complex containing a homodimer of gp130. The gp130 homodimer or gp130-LIF receptor heterodimer are thought to trigger signal transduction, while the CNTF and IL6 receptors facilitate the formation of dimers containing gp130. Receptors for IL3, GM-CSF (granulocyte macrophage-colony stimulating factor) are composed of a ligand-specific α-subunit and a common β_c-subunit, where the subscript c stands for "common." Receptors for IL2, 4, 5, 7, 9, 13, 15, and 21 are composed of a specific β-subunit and a common γ-subunit. An α-subunit contributes to an increase in the affinity of ligands to receptors but its significance in signal transduction is not known.

4.2.2 Activation of the JAK-STAT Pathway

Cytokine receptors do not have protein kinase activity but have the ability to activate nonreceptor tyrosine kinases such

Tab. 5 Protein kinase-coupled receptors (PKCRs) for growth factors, cytokines, and TGF-β, and TNF receptors.

Endogenous ligands	*Receptors*	*Events induced by ligand binding*
Group 1: Growth factor receptors with tyrosine kinase activity		
(a) Insulin, insulin-like growth factor 1(IGF-1), hepatocyte growth factor (HGF)	$\alpha_2\beta_2$ tetramer; α-subunit has ligand binding activity and β-subunit has a tyrosine kinase catalytic domain	(1) Homo- or heterodimerization of receptors (2) Transphosphorylation of tyrosine residues (3) Binding of phosphorylated tyrosine-containing motifs and SH2 domains in Grb2, PLCγ and so on. (4) Activation of SH2-containing proteins and a signal transduction cascade, Grb2-sos-ras-raf1-MAPKK-MAPK, and other cascades (5) Translocation of MAPK into nucleus and expression of specific genes
(b) Epidermal growth factor (EGF), Transforming growth factor α (TGF-α)	Homo- or heterodimer Two cysteine-rich domains	
(c) Platelet-derived growth factor (PDGF)(AA, AB, and BB dimers)	$\alpha\alpha$, $\alpha\beta$, $\beta\beta$ dimers Five Ig-like domains	
(d) Fibroblast growth factor, 23 members including acidic FGF (aFGF) and basic FGF (bFGF)	Four receptors FGFR1–4 Three Ig-like domains	
(e) Neurotrophin (NGF, brain-derived neurotrophin (BDNF), NT-3, NT-4/5)	trkA, trkB, or trkC with tyrosine kinase activity and p75 without tyrosine kinase activity	
Group 2: Cytokine receptors linked with tyrosine kinases		
(a) Growth hormone, erythropoietin (EPO), prolactin, granulocyte colony stimulating factor (G-CSF),	Homodimers	(1) Homo- or heterodimerization or oligomerization of receptors (2) Binding of Janus kinases (JAK) to receptors and activation of JAK (3) Phosphorylation by JAK of STAT (Signal transducer and activator of transcription) (4) Dimerization and translocation into nucleus of phosphorylated STATs (5) Stimulation of transcription of specific genes by dimerized STATs with or without other proteins
(b) Leukemia inhibitory factor (LIF), ciliary neurotrophic factor (CNTF), interleukin 6 (IL-6) IL-11,	Common subunit gp130	
(c) IL-3, IL-5, IL-21, granulocyte macrophage-colony stimulating factor (GM-CSF)	Common β_c subunit and specific α-subunits Common γ subunit and specific β subunits	
(d) IL-2, 4, 7, 9, 15 IL-10, 22, 28, 29 IL-12, 23	Common IL-10β-subunit and specific α-subunit Common IL—12β subunit and specific α subunit	

(e) Type 1 interferon(IFN) IFNα1, 2, 4, 5, 6, 7, 8, 10, 14, 16, 17, 21 IFN-β1, 3, IFN-τ, IFN-ω, FN-κ	Heterodimer of IFNαR1 and IFNαR2	
(f) Type 2 interferon IFN-γ	Tetramer of two IFNγR1 and two IFNγR2	
Group 3: TGFβ receptor with serine/threonine kinase activity		
Transforming growth factor β1 (TGF-β1), TGF-β2, TGF-β3, activin BMPs (bone morphogenetic proteins) (2–7)	Tetramers composed of two type I and two type II receptors Type II receptors exist as dimers and are constitutively active even in the absence of ligands	(1) Binding of TGFβ to type II receptor dimers (2) Binding of type I receptors to the TGFβ- type II receptor complex (3) Phosphorylation of type I receptor and its activation (4) Phosphorylation of SMAD (5) Heterodimerization of phosphorylated SMAD with SMAD 4 (6) Translocation of SMAD heterodimer into nucleus and stimulation of specific gene expression
Group 4: TNF receptor family		
TNF, FasL NGF	TNFR Homo-trimers FAS homotrimer NGFRp75 homodimer	(1) Binding of TNF trimer to TNFR-1, release of the inhibitory protein silencer of death domains from TNF-R1 intracellular domain (ICD) (2) Binding of the adaptor protein TRDD (TNF receptor-associated death domain) to aggregated ICD (3) TRDD recruits various adaptor proteins including caspase 8, IκB kinase, and so on. (4) Caspase 8 *triggers* a protease cascade, IκBK phosphorylates IkB that results in its dissociation from NFκB, and JNK is activated leading to phosphorylation of c-Jun (5) Initiation of apoptosis, and stimulation of specific gene transcription by NFκB and c-Jun

as JAK. JAK was named after the Roman god with two faces, Janus, because they have two kinase-like domains, although only one of them turned out to be active. Agonist binding to cytokine receptors induces the dimerization or oligomerization of receptors, which leads to activation of JAKs. JAKs bind to box 1 and box 2 of cytokine receptors. Four members of the JAK family are known; JAK1, 2, 3, and TYK2. The common receptors, gp 130, β_c, and γ, appear to interact with and activate JAK1/JAK2/TYK2, JAK2, and JAK1/JAK3, respectively. Two molecules of JAK kinases are thought to interact with ligand-bound receptor dimers and cross-phosphorylate and activate each other. Major targets of activated JAKs are STATs (signal transducer and activator of transcription). Seven members of the STAT family have been identified in the human genome (STAT1, 2, 3, 4, 5A, 5B, and 6), and each cytokine is thought to activate a specific set of STATs. STATs have SH2 domain, and the interaction between SH2 domain and phosphorylated tyrosine-containing motifs may contribute to the formation of homo- or heterodimers of phosphorylated STATs. Phosphorylated and dimerized STATs are translocated from the cytoplasm into the nucleus. STAT dimers alone or with another protein (e.g. p48) interact with DNA and stimulate transcription of specific genes.

4.3 TGF-β Receptors with Serine/Threonine Kinase Activity

Transforming growth factor-β (TGF-β) is a prototype for a large family of factors that regulate cell growth and differentiation, including activin/inhibin, bone morphogenic protein (BMP), Müllerian inhibition substances (MIS), and glial cell line-derived neurotrophic factor (GDNF). These factors have homology in amino acid sequence and tertiary structure, and all factors except MIS are dimers connected with an S–S bond. TGF-β was originally identified as a factor that causes transformation of fibroblast, and is now known to suppress proliferation of cells. Activin and inhibin were isolated as factors that stimulate or inhibit the release of follicle-stimulating hormone from cells in the pituitary, respectively. Activin is now known to function as an inducer of mesoderm. There are two kinds of inhibin dimers $\alpha\beta_A$ and $\alpha\beta_B$, and three kinds of activin homo- or heterodimers, $\beta_A\beta_A$, $\beta_A\beta_B$, $\beta_B\beta_B$. BMPs are known to induce the formation of bone and cartilage. GDNF was found as a protein that functions as a trophic factor for dopaminergic cells in the midbrain and was recently shown to support survival of motor neurons.

Receptors for TGF-β contain serine/threonine kinase activity in the intracellular part. Ligand binding to the extracellular surface of TGF receptors induces the oligomerization of type I and type II subtypes, most likely resulting in the tetramerization of two type I and two type II receptors. Type II receptors exist as dimers and are constitutively active even in the absence of TGF-β. The binding of TGF-β to type II receptor dimers causes the binding of type I receptor to the TGF-β-type II receptor complex and the phosphorylation of type I receptors. The phosphorylation of type I receptors activates its own kinase and induces the phosphorylation of downstream signal molecules named SMAD. There are eight kinds of SMAD genes in the human genome. SMAD1, 2, 3, 5, and 8 are directly phosphorylated by the type I receptor on conserved serine residues in the

carboxy terminus. Phosphorylated SMAD forms a heterodimer with SMAD4, and the heterodimer is translocated to the nucleus where it binds to transcription regulatory proteins. On the other hand, SMAD 6 and 7 inhibit the signals induced by phosphorylated SMAD. Disruption of the activity of TGF-β and SMAD family members may cause a variety of human diseases including cancer.

4.4 Intracellular Signaling: Common Pathways Triggered by GPCRs and PKCRs

Major downstream effector cascades of growth-factor receptors and cytokine receptors are the ras-MAPK and JAK-STAT pathways, respectively. There are also crossing pathways. Most cytokines also activate the ras-MAPK cascade. The src family tyrosine kinase, the adaptor protein SHC, and the carboxy-terminal domain of cytokine receptors are suggested to be involved in this response. At the same time, tyrosine kinase receptors activate STATs; for example, EGF and PDGF induce the phosphorylation of STAT1a. In addition, a pathway similar to the MAPK cascade is suggested to be present downstream of TGF-β receptors. Crosstalk between pathways triggered by GPCRs and PKCRs is also known. MAPK may be activated through GPCRs. One pathway is likely to be mediated through activation of G_q followed by activation of protein kinase C and/or increase in intracellular Ca^{2+} concentrations and another through G-protein $\beta\gamma$ subunits. In addition, activation of JAKs and STATs is reported to be caused by activation of the angiotensin II receptor (a GPCR).

Activation of PLC is mediated through different receptors. Receptors linked to G_q, G_i/G_o and growth-factor receptors may activate PLC-β1, PLC-β2/β3, and PLC-γ, respectively, and therefore any agonists interacting with these receptors may cause the increase of intracellular Ca^{2+}, and activation of Ca^{2+}-calmodulin-dependent protein kinases and protein kinase C. In addition, it has been reported that there are two kinds of PI3 kinases, which are activated by growth-factor receptors and G-protein $\beta\gamma$ subunits, respectively. PLC-γ and PI3 kinase are also known to be activated by some cytokines.

These findings indicate that the relation between receptors and intracellular signaling pathways is not straightforward and that the same outcome may be induced by activation of either GPCRs or PKCRs. Major consequences of simulation of PKCRs and GPCRs are expression of specific genes and regulation of specific protein functions, respectively. It is also possible, however, that PKCRs and GPCRs may regulate protein functions and gene expression, respectively.

5 Other Receptors

Receptors for natriuretic peptides are composed of three segments; an extracellular ligand-binding domain, a single transmembrane domain, and a cytoplasmic domain with guanylate cyclase activity and a protein kinase-like domain. There are three kinds of natriuretic peptides, ANP (atrial type), BNP (brain type) and CNP (C type), and two kinds of receptors, GC-A and GC-B. GC-A interacts with both ANP and BNP, and GC-B with CNP. Another kind of receptor for all three natriuretic peptides lacks catalytic domains, serves to internalize these peptides, and is called a *clearance receptor*. The other

type of guanylate cyclase is a soluble protein, lacks the transmembrane segment, and is activated by nitric oxide through its interaction with a heme group in the enzyme.

There are approximately 20 members in the superfamily of tumor necrosis factor receptors (TNFRs), including TNFR1, TNFR2, FAS, and CD40. Tumor necrosis factor (TNF) is a major mediator of apoptosis, inflammation, and immunity, and is thought to be involved in various diseases. TNF is a homotrimer of 157 amino acid subunits produced by activated macrophages. Most other ligands also act as a trimer. They share the homologous sequence in the domains responsible for trimerization, whereas the other regions that recognize their receptors are divergent. The receptor also forms a trimer after ligand binding. These receptors have several cysteine-rich domains in the extracellular domain, a membrane-spanning domain, and a cytoplasmic tail where some members have a death domain and a TRAF (TNF receptor-associated factor) binding site. Upon ligand binding, inhibitory proteins are released from the aggregated form of intracellular domains in the receptor and various proteins are bound there. There are six TRAFs in the human genome: TRAF1 and TRAF2 form homo- or heterodimers, and recruit IκB kinase (IKKα and IKKβ) and upstream kinases for c-jun NH_2-terminal kinase (JNK). IκB (inhibitor of nuclear factor κB (NF-κB) retains NF-κB in the cytoplasm in an inactive form, and phosphorylation of IκB results in its dissociation from NF-κB and translocation of NF-κB into the nucleus. NF-κB and c-jun stimulate transcription of specific genes in the nucleus. FAS-associated death domain (FADD) proteins are bound to the death domain, and caspase 8 is recruited to FADD. Caspase 8 initiates a proteolysis cascade leading to apoptosis. The molecular events involved in these pathways are complex and many details remain to be elucidated.

Acknowledgments

We are deeply indebted to Dr. J. Wess in N.I.H. for detailed comments and corrections throughout the whole manuscript. We also thank Dr. K. Inoue in National Institute of Health Sciences, Dr. Hiroyasu Furukawa in Columbia University, Dr. U. Langel in Stockholm University, Dr. G. Berstein in Wyeth Pharmaceuticals for reading a part or all of this manuscript and giving us valuable comments.

Keywords

Agonist
A ligand that interacts with a receptor to activate and produce a defined response.

Antagonist
A ligand that interacts with a receptor to block the effects of an agonist.

Drug
A compound that, via its interaction with a defined receptor target, reverses a disease phenotype. Drugs are characterized by their selectivity, safety, and pharmacokinetic properties, which are consistent with their reaching their target site of action within the body.

G-protein–Coupled Receptors
The best-known receptor family through which the largest number of known drugs act to produce their pharmacological effects, for example, cimetidine (histamine H_2 receptor), and propranolol (β-adrenoceptor). These receptors are defined by a common structure of seven transmembrane domains and their interactions with members of the heterotrimeric G-protein family.

Heterotrimeric G-protein
A family of oligomeric proteins consisting of three subunits (α, β, and γ). These protein complexes transduce signals from activated GPCRs to a variety of intracellular signaling cascades.

High-throughput Screening
Testing of large sets of compounds (typically 100 000–2 million) for interaction with a receptor target.

Ion Channels
Typically composed of protein multimers that form channels to conduct anions and/or cations through the membrane (e.g. the neuronal nicotinic receptor). Activation of ion channels can occur by ligand activation (e.g. nicotine, glutamate), by changes in membrane voltage, pH, mechanical distension, and temperature.

Ligand
A defined chemical entity that is natural (e.g. histamine) or synthetic and (e.g. propranolol) that binds to a receptor.

New Chemical Entity (NCE)
A compound with potential druglike properties.

Orphan Receptor
A receptor, identified on the basis of its structural motif for which the endogenous ligand and physiological function have not yet been identified.

Receptor

1. A membrane associated protein that selectively responds to extracellular messenger molecules to alter cellular function to maintain homeostasis and normal cell/tissue function. Receptors comprise two major classes, G-protein–coupled receptors (GPCRs) and ion channels.

2. A drug target – a concept that expands the definition of a receptor to intracellular sites that include enzymes, transporters, and signal transduction elements.

SAR
Dose/concentration dependent differences in the efficacy (agonist or antagonist) of compounds in a ligand series, which can be associated with changes in chemical structure.

Therapeutic Index
The ratio between the dose at which a drug or NCE produces efficacy in a disease state or disease model, and the dose at which it produces side effects.

Receptors, located on both the cell surface and within the cell are the defined molecular targets through which drugs produce their beneficial effects in various disease states. Initially conceptualized over a century ago by Ehrlich and Langley, receptor concepts and receptor theory have undergone continuous modification as their behavior in normal and disease states/tissues have been more clearly characterized. Since the isolation of the nicotinic acetylcholine receptor (nAChR) from the *Torpedo*, some 50 years ago, new techniques of molecular biology have made it relatively routine to isolate receptors, including orphan receptors. Once these have been validated, they can be used in conjunction with high- throughput screening approaches to identify ''hits,'' molecules that bind with relatively high affinity to these targets. Such hits can then be optimized to druglike entities using combinatorial/parallel synthesis technology platforms to yield clinical candidates that are potent, efficacious, and bioavailable entities with appropriate safety profiles.

1 Drug Discovery

Drug discovery, the process of identifying and developing novel chemical entities (NCEs) to treat human disease states, has entered the new century with a wealth of sophisticated technologies and information generation platforms, which have the potential to allow more rapid development of new drugs with improved selectivity and safety profiles.

Successful drugs from the pharmaceutical industry that include small-molecule drugs (NCEs), biologicals, vaccines, and antibodies, have resulted in an increase in human life expectancy, with the concomitant expectation that new drugs will be available for the aging population, which will improve the quality of life while adding to its span. The draft map of the human genome has led to the possibility of understanding diseases at a level of precision that was never before possible. Thus, in the last decade, there has been an exponential increase in understanding the potential pathophysiologies of disorders like pain, diabetes, some forms of

cancer, and neurodegenerative processes (Alzheimer's and Parkinson's diseases).

The challenge in effectively using the copious information now available for disease-related gene identification and the molecular targets involved in the cause(s) of various diseases is how to handle and productively focus the bewildering flow of data, much of it archival, to cost-effectively discover and develop new drugs – a challenge that has given rise to key disciplines like bio- and chemo-informatics.

Irrespective of compound or drug target sources, more productive high-throughput screening (HTS) processes, and more detailed structural information on putative drug targets, it is clear that continued success in the drug discovery process will depend on the iteration and integration of lead compound identification and optimization through the hierarchical complexity of *in vitro* and *in vivo* assays that measure efficacy, selectivity, side effect liability, absorption, distribution, metabolism and excretion (ADME), and potential toxicity. To do this in an effective manner, it is critical to understand how existing knowledge of drug targets has evolved and what the realistic potential is for identifying, validating, and prioritizing new ones.

2 Cellular Communication

The transfer of information between cells and the subsequent integration of multiple inputs that are necessary to maintain cellular homeostasis and tissue viability – under both normal and adverse disease-related conditions – involves a variety of different external signaling modalities. These include: temperature, membrane potential, mechanical distension and stress, alterations in ion (H^+/K^+) concentrations, pheromones, oderants, as well as more traditional neurotransmitters, neuromodulators, and hormones. These physical stimuli and endogenous chemicals elicit their effects through interactions with cell surface targets, usually proteins, which are termed *receptors* (Table 1). Once receptors are activated by an *agonist* ligand, a compound capable of producing a cellular response, they transduce or couple the energy associated with the binding event to a cellular effect via a signal transduction process(es) involving protein–protein interactions or second messenger signaling systems, for example, G-proteins, protein kinase or phosphatase modulation, alterations in lipid metabolism, calcium translocation, and so on, to produce acute or more long-term effects on cell and tissue function. Thus, neurotransmitters, neuromodulators, and hormones can produce transient increases in second messengers like cyclic AMP or inositol triphosphate (IP_3) or more long-term changes that involve changes in gene expression through activation of transcription factors.

Alterations in receptor function occur by: (1) a functional overstimulation of receptors with their consequent desensitization, a phenomenon resulting from excess ligand availability or an enhanced coupling of the ligand-activated receptor to second messenger systems, or (2) a reduction in stimulation resulting from decreased ligand availability or dysfunctional receptor coupling processes.

Drugs that effectively treat human disease states by restoring disease-associated defects in signal transduction can act either by replacing endogenous transmitters, for example, L-dopa treatment to replace the dopamine (DA) lost in Parkinson's disease, or blockade of excess agonist stimulation,

Tab. 1 Drug recognition sites classified as receptors.

Type	*Class*	*Examples*
Receptor	GPCR	Dopaminergic, adrenergic, $GABA_B$, mGluR
	Ion channel	
	LGIC	NMDA, nicotinic, $GABA_A$
	VGIC	Na_v, Ca_v
	Others	ASIC, TRPV
	Enzyme Assoc. R	
	Tyrosine kinase	PDGF, EGF, Trk
	Others	CNTF, cytokine
	Nuclear hormone R	
	Steroid R	GR, PR
	Others	PPAR, RAR
Neurotransmitter Transporter	Plasma membrane neurotransmitter transporters	SERT, NET, GAT, DAT
Enzyme	Cell surface/ extracellular	ACE, NOS, HMG CoA reductase, acetylcholinesterase
	Intracellular	Caspase, CDK, ROCK DNA polymerase

Note: GABA: γ-aminobutyric acid; mGluR: metabotropic glutamate receptor; LGIC: ligand-gated ion channel; VGIC: voltage-gated ion channel; NMDA: *N*-methyl-D-aspartic acid; ASIC: acid sensing ion channel; TRPV: transient receptor potential vanilloid; PDGF: platelet-derived growth factor; EGF: epidermal growth factor; CNTF: ciliary neurotrophic factor; GR: glucocorticoid receptor; PR: progesterone receptor; PPAR: peroxisome proliferator-activated receptor; RAR: retinoic acid receptor; SERT: serotonin transporter; NET: norepinephrine transporter; GAT: GABA transporter; DAT: dopamine transporter; ACE: angiotensin-converting enzyme; NOS: nitric oxide synthase; CDK: cyclin-dependent kinase; ROCK: rho-dependent kinase.

for example, the histamine H_2 receptor antagonist, cimetidine, which blocks histamine-induced gastric acid secretion and thus reduces ulcer formation. Of the approximately 450 targets through which known drugs act, 71% are receptors in the G-protein–coupled receptor (GPCR), ion channels, or neurotransmitter transporter (SCDNT) families. Of these drugs, approximately 90% produce their effects by antagonizing the actions of endogenous agonists

Enzymes, by producing products that regulate second messenger availability, for example, adenylyl cyclase-catalyzed production of cyclic AMP or phosphodiesterase-mediated degradation of cAMP, or by modifying protein targets, for example, by adding (protein kinases) or removing (protein phosphatases) phosphates on serine or threonine residues, serve a similar role in cellular homeostasis, and as such, also represent key drug targets that can be conceptually included in the category of receptors.

The seminal concept that therapeutic agents produce their effects by acting as ''magic bullets'' at discrete molecular targets on tissues within the body is attributed to Ehrlich and Langley, who at the beginning of the twentieth century independently generated experimental data that led to the evolution of the ''lock and key'' hypothesis. A ligand (L) thus acted as

the unique ''key'' to selectively modulate receptor (R) activity, the latter functioning as the ''lock'' for the ''entry'' of external signals into the cell. In this model, an agonist ligand forms an RL complex and has the ability to ''turn'' the lock (Equation 1), whereas a receptor antagonist would occupy the lock and prevent agonist access.

$$\text{Receptor} + \text{ligand} \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} \text{RL} \longrightarrow \text{Signaling event} \qquad (1)$$

Despite quantal advances in the technology used to study receptor interactions that have occurred over the past century, the receptor–ligand (RL) concept and the similar enzyme–substrate (ES) complex have remained the conceptual foundations for understanding receptor and enzyme function, disease pathophysiology, and medicinal chemistry-driven approaches to drug discovery. Over the past decade, however, with the explosion in the number and diversity of receptors driven by receptor cloning approaches and the mapping of the human genome, there has been an increased appreciation of the inherent complexity of receptor function.

At one time, it was thought that a receptor-mediated response was a predictable, linear process that involved ligand-induced activation of a protein monomer and its signal transduction pathway independently, or with very little influence, from other membrane proteins. It has become increasingly evident, however, that receptors can physically interact both with one another and with other membrane proteins. Numerous examples exist of receptor coexpression and interactions, for example, $GABA_BR1$ (γ-aminobutyric acid) and $GABA_BR2$, dopamine with somatostatin, and $GABA_A$ receptors and opioid receptors with α_2-adrenoceptors. These interactions are often necessary to obtain functional cell surface receptors and allow interactions with one protein partner to modulate the function of the entire signaling complex. Effects of receptors on protein subunits can be mediated through orthosteric sites, for example, the site that the endogenous ligand(s) interact with, or through allosteric sites (e.g. the benzodiazepine (BZ) site in the $GABA_A$ receptor, and the glycine receptor on the *N*-methyl-D-aspartate (NMDA) receptor complex). More recently, allosteric interactions with GPCRs (muscarinic adenosine A_1) and neurotransmitter transporters (NET) have been reported. Integration of the functional effects of signal transduction pathways also affects receptor functions in a cell-specific manner (receptor cross talk). There also exist several discrete classes of receptor-associated proteins including receptor-activity-modifying proteins (RAMPs) and trafficking chaperones, which currently number in the many hundreds and play key roles in cellular events like receptor trafficking from the endoplasmic reticulum to the cell surface, and modulation of cell surface responses. Examples of the complexity of receptor signaling at the postsynaptic level include the NMDA receptor, where proteomic analysis demonstrated more than 70 proteins other than the receptor potentially involved in the function of the receptor complex; and the ATP-sensitive $P2X_7$ receptor, where a signaling complex comprised of 11 proteins including laminin-3, integrin 2, actin, supervillin, MAGuK, three heat shock proteins, and phosphatidylinositol 4-kinase; and the receptor protein tyrosine phosphatase (RPTP) was identified, which appears to modulate $P2X_7$ receptor function through control of its phosphorylation state.

3 Receptor Concepts

Receptor theory is based on the classical Law of Mass Action as developed by Michaelis and Menten for the study of enzyme catalysis. The extrapolation of classical enzyme theory to receptors is, however, an approximation. In an enzyme–substrate (ES) interaction, the substrate S undergoes an enzyme-catalyzed conversion to a product or products. Because of the equilibrium established, product accumulation has the ability to reverse the reaction process. Alternatively, the latter can be used in other cellular pathways and is thus removed from the equilibrium situation or can act as a feedback modulator to alter the ES reaction either positively or negatively (Equation 2).

$$\text{Enzyme} + \text{Substrate} \rightleftharpoons \text{ES} \rightleftharpoons \text{E} + \text{Product} \quad (2)$$

For the receptor–ligand interaction, binding of the ligand to the receptor to form the RL complex results in a response driven by the thermodynamics of the binding reaction that leads to functional changes in the target cell (Equation 1). Whereas conformational changes occur in the ligand, the receptor, or both, there is no chemical change in the ligand resulting from the RL interaction such that there is no chemical product derived from the ligand that results from the RL interaction. Despite events such as receptor internalization, receptor phosphorylation, second messenger system activation, and so on, the bound ligand is chemically unchanged by the binding event, and thus, there is no equilibrium established between the RL complex and the consequences of receptor activation.

After the formation of an RL complex, a functional response to receptor activation can be related to the concentration of the ligand that is present (Fig. 1a). *Occupancy theory*, developed by Clark in 1926, is based on a dose/concentration-response relationship. This theory has undergone continuous refinement on the basis of experimental data to aid in further delineating the increasingly complex concept of ligand efficacy and to accommodate allosteric site modulation of receptor function, ternary complex models (TCM), and their extension to constitutively active receptor systems – those that are functional in the absence of an identified ligand.

3.1 Occupancy Theory

The basic premise of Clark's occupancy theory, based on Michaelis–Menten theory, was that the effect produced by an agonist was dependent on the number of receptors occupied by that agonist, a reflection of the agonist concentration present. This theory was developed from Clark's observations that acetylcholine (ACh) receptor antagonists such as atropine caused a rightward shift in the ACh dose-response (DR) curve in muscle preparations when plotted logarithmically. The basic tenets of occupancy theory were as follows: (1) the RL complex was assumed to be reversible; (2) the association of the receptor with the ligand to form the RL complex was defined as a bimolecular process with dissociation being a monomolecular process; (3) all receptors in a given system were assumed to be equivalent to one another and able to bind ligand independently of one another; (4) formation of the RL complex did not alter the free (F) concentration of the ligand or the affinity of the receptor for the ligand; (5) the

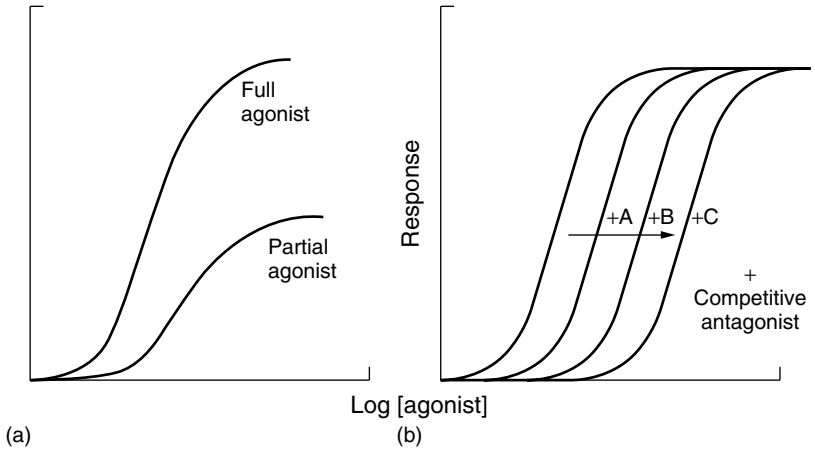

Fig. 1 Dose-response curve. The addition of increasing concentrations of an agonist ligand causes an increase in a biological response. Plotted on a logarithmic scale, a sigmoidal curve is obtained. (a) A full agonist produced a maximal response, whereas a partial agonist reaches a plateau that is only part of the response seen with a full agonist. (b) In the presence of antagonist concentrations A, B, C, the dose-response curve is progressively moved to the right. Increasing agonist concentrations overcome the effects of the antagonist.

response elicited by receptor occupancy was directly proportional to the number of receptors occupied; and (6) the biological response was dependent on attaining an equilibrium between R and L according to Equation 1.

Although it is not always possible to determine the concentration of free ligand (F) or that of the RL complex, rearranging the latter, the equilibrium dissociation constant, K_d, equaling $k - 1/k + 1$, can be derived from the equation:

$$K_d = \left(\frac{[R][L]}{[RL]} \right) \qquad (3)$$

and is equal to the concentration of L that occupies 50% of the available receptors.

Antagonist interactions with the receptor were defined by Gaddum as being the result of receptor occupancy with the antagonist ligand being unable to elicit a functional response. Antagonists thus block agonist actions. Agonists overcome the effects of a competitive (e.g. reversible/surmountable) antagonist when their concentration is progressively increased (Fig. 1b) such that in the presence of increasing fixed concentrations of a competitive antagonist, a series of parallel agonist DR curves can be generated that shift progressively to the right (Fig. 1b). A Schild regression relationship, a plot of log (DR-1) versus the log antagonist concentration (Fig. 2), can be used to derive the pA_2 value for an antagonist from the intercept of the abscissa. The pA_2 value is the negative logarithm of the affinity of an antagonist for a given receptor in a defined biological system and is equal to $-\log_{10} K_B$ where K_B is the dissociation constant for a competitive antagonist with a slope of near unity. Not all antagonists are competitive. Non- or uncompetitive antagonists that act at allosteric sites or that bind irreversibly to the agonist site have slopes that are

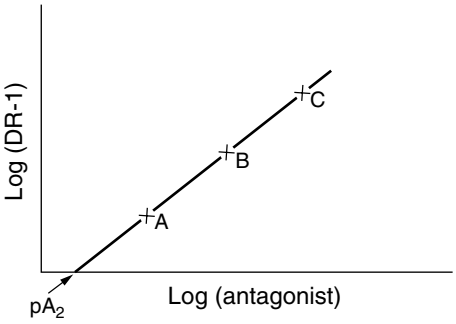

Fig. 2 Schild plot regression. Data from Fig. 1(b) for antagonist concentrations A, B, and C can be plotted by the method of Schild (29) to yield a pA_2 value, a measure of antagonist activity. A slope of unity indicates a competitive antagonist.

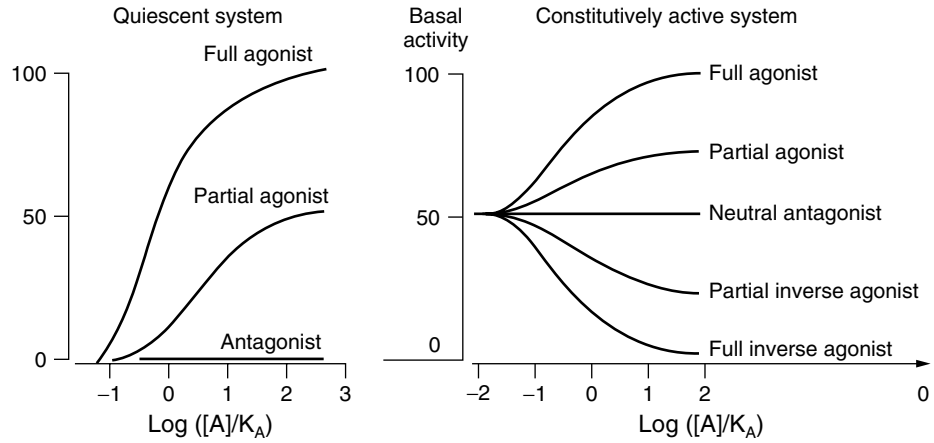

Fig. 3 Efficacy in quiescent and constitutively active systems. In a quiescent system, three types of ligands can be defined, full agonist, partial agonist, and antagonist, depending on the response elicited. In a constitutively active system, an antagonist from a quiescent system is defined as a neutral antagonist with ligands that inhibit the activity of the constitutively active system and are defined as full and partial inverse agonists depending on the degree of inhibition.

significantly less than unity. The Schild plot can thus be used to determine the mechanism by which an antagonist produces its effects.

Occupancy theory was modified by Ariens on the basis of data showing that not all cholinergic agonists were able to elicit a maximal response in a skeletal muscle preparation, even when administered at supramaximal concentrations. This led to the introduction of the concept of the *intrinsic activity* of a ligand. A full agonist was defined as having a value of 1.0 with the value for an antagonist being zero. However, many compounds were subsequently identified that bound to the receptor but were able to only produce a portion of the response seen with a full agonist. These were defined as partial agonists (Fig. 1a). By definition, these compounds were also partial antagonists.

Other agonists have also been identified that produce a response greater than the previously defined full agonist. These have been termed *super agonists*. One example

is the muscarinic cholinergic receptor agonist, L 670,207 (Fig. 3), an arecoline bioisostere that was 70% more active than arecoline and thus had an intrinsic activity of 1.7. From the activity seen in response to L 670,207, the system that is used to characterize these muscarinic agonists was obviously capable of a greater response than that seen with arecoline, making the latter compound a partial agonist.

The partial agonist concept was additionally refined by Stephenson in introducing the concept of *efficacy*, ε, which differed from intrinsic activity in that the latter was defined as a proportion of the maximal response [effect = (RL)]. This concept was extended to situations in which a maximal response to an agonist could occur when only a small proportion of the total number of receptors on a tissue were occupied (a condition termed *receptor reserve*), as in the situations when receptors were inactivated by alkylating agents. This resulted in a nonlinear occupancy relationship with the response then being defined as the stimulus, S, a product of the fraction of receptors occupied and the ligand efficacy. A nonlinear functional response clearly complicates data interpretation, especially when spare receptor or receptor reserve concepts are introduced to rationalize individual data sets. An additional issue in defining efficacy was the degree to which the receptor activation event and its blockade by antagonists was measured through events that were spatially and temporally removed from the receptor activation event, and also the degree to which the response could be amplified through cofactor and signal transduction cascades.

Kenakin described ligand-mediated responses in a given tissue in terms of four parameters: (1) receptor density; (2) the efficiency of the transductional process; (3) the equilibrium dissociation constant of the RL complex; and (4) the intrinsic efficacy of the ligand at the receptor. *In vivo*, receptor occupancy for exogenous ligands is primarily dependent on pharmacokinetic parameters, whereas that for native endogenous ligands is most probably under intrinsic homeostatic controls including rates of production, release, metabolism, and reuptake of ligands.

Classical receptor theory assumed that affinity and efficacy were independent parameters, suggesting that no consistent relationship existed between the affinity of a ligand and its ability to elicit a full response. A ligand with relatively low affinity ($<10^{-6}$ M) could still be a full agonist when a sufficient concentration interacted with the receptor. With the discovery of constitutive receptor activity, it seems that this lack of a consistent relationship is more reflective of an inability to measure receptor-mediated activity than a potency disconnect. Thus, one may conclude that all ligands have efficacy if the appropriate system is used to measure this parameter.

The relationship between the receptor and ligand in the classical lock and key model with the RL interaction resulting in no change in the receptor conformation essentially described a static situation. In 1958, however, Koshland described the induced fit model of the ES complex, where substrate binding to the enzyme caused a change in the three-dimensional structure of the protein, leading to a change in activity. Together with the pioneering work of Hill on hemoglobin allosterism, the concept of allosteric modulation of receptor function was proposed.

3.2 Rate Theory

On the basis of experimental data showing the persistence of antagonist-mediated responses and agonist ''fade'' where maximal responses occur transiently, to be followed by lesser responses of longer duration and agonist-mediated blockade of agonist effects, Paton modified the concept of occupancy to include a chemically based rate term. According to rate theory, it was not only the number of receptors occupied by a ligand that determined the tissue response but also the *rate* of RL formation. The resultant effect, E, was considered equal to a proportionality factor, ϕ, that included an efficacy component and the velocity of the RL interaction, V. Thus,

$$E = \omega Veq \qquad (4)$$

The rate of RL formation, like that of neurotransmitter release, was measured in quantal terms with discrete ''all or none'' changes in receptor-mediated events. Pharmacokinetic considerations also play a major role determining the rate of RL formation.

The primary factor delineating occupancy and rate theory seemed to be the dissociation rate constant. Thus, if this factor was large, the ligand was an agonist; if the factor was small, reducing the quantal response to receptor occupancy, the ligand functioned as an antagonist. The kinetic aspects of rate theory did not, however, take into account the efficacy of transductional coupling and the potential for amplification after the initial binding event leading to its description as ''a provocative conceptualization ... with limited applicability,'' a phrase that can be applied to many of the newer aspects of receptor theory.

4 Receptor Complexes and Allosteric Modulators

The studies of A.V. Hill on the binding of oxygen by hemoglobin demonstrated that identical binding sites on protein oligomers could influence one another such that the binding of the first ligand (in the case of hemoglobin in oxygen) facilitated the binding of a second, identical ligand, and so on for sequentially bound ligands such that the saturation curve describing the interaction of the ligand with its recognition site is steeper than that which would be predicted from classical Michaelis–Menten kinetics. The process of one ligand, homologous or heterologous, interacting with the binding of another is thought to occur by a cooperative, conformational change in the binding protein for the second ligand from a site adjacent to the ligand recognition site. Koshland's induced fit model extended these findings, leading to the development of two models of cooperativity or allosterism: the *sequential or induced fit* model described by Koshland; and the *concerted model* of Monod, Wyman, and Changeux, the key elements of which are outlined in Table 2.

Both models assume the existence of oligomeric protein units existing in two states that are in equilibrium with one another in the absence of ligand. Ligand binding induces a conformational change in the protein(s), moving the equilibrium of the two states to favor that with the higher affinity for the ligand. This in turn alters the kinetic and functional properties of the oligomeric complex. This model has been further refined in terms of *ligand-stabilizing conformational ensembles.*

The site on a receptor that defines its pharmacology and membership of

Tab. 2 Allosteric receptor models.

Monod, Wyman, Changeux Concerted Model
Receptor complex is a multicomponent oligomer comprised of a finite number of identical binding sites.
Subunits are symmetrically arranged each having a single ligand binding site.
Receptor complex exists in two conformational states, one of which has a preference for ligand binding.
Conformational transition state involves a simultaneous shift in the state of all subunits.
No hybrid states exist implying cooperativity.
Koshland Nemethy Filmer Sequential Model
Receptor complex is a multicomponent oligomer with symmetrically arranged protomers each with a single ligand binding site.
Protomers exist in two conformational states with transition induced by ligand binding.
Receptor symmetry is lost on ligand binding.
Hybrid states of the receptor complex can be stabilized by protomers.
Stabilization is equivalent to negative cooperativity.

a particular receptor superfamily, for example, 5HT, nicotine, and so on, is termed the *orthosteric site*. Ligands that bind to this receptor have a spatial overlap for the binding site such that their binding is mutually exclusive (unless an antagonist covalently binds to the orthosteric site). In contrast, the *allosteric site* (of which there may be more than one associated with a single orthosteric site and which can affect that site) is distinct from the latter in that ligands that bind to the allosteric site(s) can produce effects on ligand binding and efficacy to the orthosteric site through an indirect, conformational modulation of this site, which probably involves alterations in either the association or dissociation rates of the orthosteric ligand. While much of the early work on allosterism derived from studies on enzymes and ligand-gated ion channels (LGICs), it is now clear that GPCRs that were once considered as monomeric proteins with only an orthosteric site are now known to contain allosteric sites and can form oligomeric complexes. The concept of allosterism becomes more complex when considering multiple ligand sites on a receptor that have different pharmacological profiles, for example, when the ligand recognition sites are totally heterogeneous.

The identification of allosteric ligands that can have both positive and negative effects on the function of the orthosteric site occurred in a largely serendipitous manner. The first drug identified as an allosteric modulator was the BZ, diazepam, which has anxiolytic, hypnotic, and muscle relaxant activities and produces its effects by facilitating the actions of the $GABA_A$ receptor. Unlike the majority of directly acting $GABA_A$ receptor agonists, diazepam has a relatively safe side effect profile.

Allosteric modulators have three apparent advantages over drugs acting via orthosteric sites: their effects are saturable such that there is a ceiling effect to their activity, which results in a good margin of safety in human use; their effects are selective, and as mentioned earlier, frequently ''use-dependent.'' Thus, the actions of an allosteric modulator occur only when the endogenous orthosteric ligand is present. In the absence of the latter, an allosteric

modulator is theoretically quiescent and may thus represent an ideal prophylactic treatment for disease states associated with sporadic or chronotropic occurrence. Finally, allosteric modulators are considered to be more specific in their effects, partly because of the nature of their binding sites that are distinct from the orthosteric site and partly because of the extent to which their effects depend on the degree of cooperativity between the allosteric and orthosteric sites.

The ''cys-loop'' family of LGICs including the $GABA_A$, glycine, $5HT_3$, and nicotinic cholinergic receptors are the best characterized of the allosterically regulated receptors. GPCRs are also subject to allosteric modulation. The families identified to date demonstrating this property include adenosine (P1) and α-adrenergic, dopamine, chemokine, $GABA_B$, endothelin, metabotropic glutamate, neurokinin-1, P2Y, and muscarinic cholinergic, as well as some members of the 5HT superfamily. The cone snail conotoxin, ρ-TIA is an allosteric modulator of the α_{1B}-adrenoceptor. Changes in GPCR function resulting from alterations in the ionic milieu also reflect the potential for allosteric modulation of receptor function.

5 Ternary Complex Models

The ternary complex model or TCM describes allosteric interactions between orthosteric and allosteric sites present on a single protein monomer. It can also be extended to reflect the other two-state interactions involving sites on adjacent proteins and the effect of signaling proteins, for example, G-proteins on the function of the receptor. Christopoulos notes allosteric interactions as being reciprocal such that the effects of a ligand A on the binding properties of ligand B also imply an effect on the binding of ligand B on the properties of ligand A. Similarly, because GPCRs alter the conformation of G-proteins to elicit transductional events and an alteration in cell function, changes in G-protein conformation and interactions alter receptor function, and this may be reflected in desensitization.

6 Constitutive Receptor Activity

A basic principle of receptor theory is that when a receptor is activated by a ligand, the effect produced by the ligand is proportional to the concentration of the ligand; for example, it follows the Law of Mass Action. It is now becoming apparent that receptors spontaneously form active complexes as a result of interactions with other proteins. This is especially true when receptor cDNA is *overexpressed* in cell systems such that the relative abundance of a receptor is in excess of that normally occurring in the native state, or associates with proteins that reflect the host cell milieu in which the receptor is expressed, rather than an intrinsic property of the receptor in its natural environment. This is a major issue in the characterization of ligand efficacy. A spontaneous interaction between receptor and effector can occur more frequently in a system where the proteins are in excess and where the normally present factors that control such interactions are absent. This is shown graphically in Fig. 3, where constitutive activity is shown in the range of 0–50 and where the theoretical effects of inverse agonists, full and partial, are shown. A quiescent system that is more reflective of classical receptor theory shows a full agonist, partial agonist, and what

is now defined as a neutral antagonist. Constitutive receptor activation has been described in terms of *protein ensemble* theory and in terms of *allosteric transition*, where changes in receptor conformation can occur through random thermal events.

7 Efficacy Considerations

Historical receptor theory describes a ligand efficacy continuum, with full agonism at one end and full antagonism at the other. Between the two ends of this continuum lie partial agonists that, as already noted, imply that ligands can also be partial antagonists. Antagonism *per se* implied that a ligand could bind to a receptor without producing any effect and limiting access to the native agonist – block receptor activation. Such a compound is now called a *neutral antagonist*.

With the ability to measure constitutive receptor activity, some compounds, for example, the β2-adrenoceptor antagonist, ICI 118551, inhibited constitutive activity, thus functioning as an *inverse agonist* or *negative antagonist*.

The actions of a competitive antagonism can be surmounted by the addition of increasing concentrations of the agonist ligand, resulting in a functional DR curve that undergoes a rightward shift with approximately the same shape and maximal effect (Fig. 1). Noncompetitive or uncompetitive antagonists interact at sites distinct from the agonist recognition site, and can modulate agonist binding either by proximal interactions with this site from a site adjacent to the recognition site or by allosteric modulation. The effects of noncompetitive antagonists are usually not reversible by the addition of excess agonist. This type of antagonism, whether competitive or noncompetitive, occurring at a distinct molecular target is known as *pharmacological antagonism* and involves the interactions between ligands and the receptor site (Fig. 4). In contrast, *functional antagonism* refers to a situation in which an antagonist that does not interact with a given receptor can still block the actions of an agonist of that receptor, and is typically measured in intact tissue preparations or whole animal models.

In the cartoon outlined in Fig. 4, neurotransmitter A released from neuron A interacts with A-type receptors on neuron B. Antagonist α can block the effects of A on cell B by interacting with A receptors. Antagonist α is thus a pharmacological

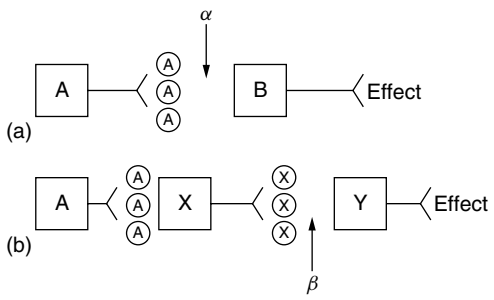

Fig. 4 Pharmacological versus functional antagonism. In panel (a), neurotransmitter A is released from neuron A, directly interacting with neuron B to produce a functional response. Antagonist blocks the effects of A, a direct pharmacological antagonism of the effects of A. In panel (b), neurotransmitter A is released from neuron A, directly interacting with neuron X, which in turn releases neurotransmitter X, which acts on cell Y to produce a functional response. Antagonist blocks the effects of X on cell Y, but in the absence of other data on the actions of antagonist, seems to block the functional effects of A because of the circuitry involved. Antagonist thus acts as a functional antagonist.

antagonist of A receptors. In the second example in Fig. 4, neuron A releases neurotransmitter A, which interacts with A-type receptors located on neuron X. In turn, neuron X releases neurotransmitter X that interacts with X-type receptors on neuron Y. Antagonist β is a competitive antagonist that interacts with X receptors to block the effect of neurotransmitter X, and in doing so, indirectly blocks the actions of neurotransmitter A. Antagonist β is thus a pharmacological antagonist of receptors for the neurotransmitter X, but a functional antagonist for neurotransmitter A.

In interpreting functional data in complex systems, it is always important to consider the possibility that a ligand has more than one effect mediated through a single class of receptor. For this reason, in advancing new ligands from *in vitro* evaluation to more complex tissue systems or animal models, it is extremely helpful to have a ligand-binding profile, for example, the activity of a compound at a battery of 90 or more receptors and enzymes (a Cerep profile), to fully understand any new findings. For instance, when a ligand for a new receptor is advanced to animal models and found to elicit changes in blood pressure, it is extremely helpful to know whether in addition to its defined activity at the new receptor, it has some other properties that relate to the blood pressure effects, rather than assuming that some unknown mechanism related to activation of the new receptor has cardiovascular-related liabilities.

8 Receptor Dynamics

Receptors, present in their active form at the cell surface are not static entities. Ligand binding, alterations in gene function and tissue dysfunction due to disease, trauma or aging, can alter the number, half-life, and responsiveness of receptors, channels, and transporters. Receptors turnover as a normal consequence of cell growth, with half-lives that vary between hours and days. Ligand binding can result in receptor internalization through phosphorylation-dependent events often initiated as a result of the ligand-binding process, exposing serine and threonine residues in the receptor protein. Histamine H_2 antagonists acting as inverse agonists in constitutively active systems can upregulate their cognate receptors, potentially increasing cell sensitivity. It is reasonable to assume that the target cells for endogenous effector agents, neurotransmitters, neuromodulators, and neurohormones operate under tonic control, one example being chronotropic, varying with the circadian rhythm of the organism. In contrast, the effects of exogenously administered ligands, for example, drugs, are rarely under normal homeostatic control, and as a result, their effects frequently become blunted on repeated administration or when they are administered in controlled release forms. Therefore, it should not be a surprise that the majority of effective therapeutic agents are antagonists of receptor function.

In Parkinson's disease, the presynaptic nerve cells in the *substantia nigra* that normally produce dopamine die as the result of an as yet unknown disease etiology. This defect results in a decrease in dopamine levels and a consequent hypersensitivity of postsynaptic responses as the cellular homeostatic events attempt to compensate for a lack of endogenous ligand. Agonists that rapidly desensitize a receptor, for example, ATP at the $P2X_3$ receptor and nicotine at the $\alpha4\beta2$ receptor,

appear to be antagonists because their net effect is to attenuate the normal receptor response.

9 Receptor Nomenclature

Even before the publication of the draft maps of the human genome, the techniques of molecular biology had already resulted in an explosion in the number of putative receptor families and subtypes within families, as well as classes of receptors known as *orphan receptors*. These were structurally related members of receptor classes for which the endogenous ligand and associated function was unknown.

New receptors have been (and continue to be) identified in different laboratories often simultaneously, leading to different names causing considerable confusion in the literature. The *International Union of Pharmacology* (IUPHAR) has undertaken the development of a systematic nomenclature system, based in part on naming families of receptors for their cognate endogenous ligands. The deliberations of the various committees enlisted to devise a systematic nomenclature are published periodically in *Pharmacological Reviews*. Compendiums are also regularly published, the most current and comprehensive being *The Sigma-RBI Handbook*.

10 Receptor Classes

Receptors can be divided into four major classes (Table 1): heptahelical, 7-transmembrane (7-TM) GPCRs, ion channels, transcription factor receptors and enzyme-associated receptors. Of these, the 7-TM receptors have historically represented the most fertile class for drug discovery, as these have been the most studied. This receptor superfamily includes receptors for the bioamine neurotransmitters (5-HT, dopamine, etc), peptide hormones, and lipid signaling molecules. Ion channels are further subdivided into LGIC, voltage-sensitive calcium channel (VSCC) and potassium (Kir), and ion/pH-modulated (ASIC) subtypes, all of which have similar but distinct, multimeric structural motifs. TRPV (transient receptor potential vanilloid) ion channels can be modulated by temperature, for example, vanilloid receptors. The largest group within the transcription factor receptor superfamily is the nuclear hormone receptors that include receptors for steroids (glucocorticoid (GR), progesterone (PR), mineralocorticoid (MR), androgen (AR)), and nonsteroids (thyroid hormones (TRs), PPARs, the retinoic acid receptors (RXR, RAR), and vitamin D_3 (VDR)). In addition, many orphan receptors have been identified with structural similarity to the known transcription factor receptors. The enzyme-associated receptor superfamily is a family of single- or multi-subunit proteins, which contain a subunit with a single transmembrane domain. The largest groups within this superfamily are the single-subunit–tyrosine kinase receptors, such as the PDGF (platelet-derived growth factor) and EGF (epidermal growth factor) receptors, and the multimeric complexes that utilize kinases such as the JAK-type kinases for their signal transduction (e.g. cytokine and growth hormone receptor families). Also included are receptors with serine/threonine kinase or guanylyl cyclase activity.

In addition to this multitude of receptor classes, further complexity in conceptualizing receptors as distinct, classifiable

entities is exemplified by recent findings related to GPCRs. By implicit definition, these receptors produce their physiological effects by coupling through the G-protein family. However, there are instances in which ion channels produce their effects by coupling through G-proteins. Receptor classification thus has few absolutes.

10.1 G-protein–Coupled Receptors

The 7-TM motif of GPCRs based on the X-ray structure of rhodopsin is a single protein comprised of approximately 300–500 amino acids with discrete amino acid motifs in the transmembrane (TM) regions and on the C-terminal extracellular loop, determining the ligand specificity of the receptor and those on the amino terminal and intracellular loops designating G-protein interactions. For example, RL interactions for many of the bioamine neurotransmitter receptors are thought to occur within a pocket in the 7-TM motif that is generically designated to lie between TMs III, IV, and VI. Posttranscriptional alternative splicing can alter the GPCR to create isoforms that may be species, tissue, and disease-state dependent.

The number of GPCRs present in the human genome, including orphan receptors, has been estimated to be 1000–2000 with over 1000 of these coding for odorant and pheromone receptors. Currently of greatest interest in drug discovery efforts are the 367 nonchemosensory GPCRs, over 100 of which remain "orphan receptors."

GPCRs are organized into four main families. *Family 1* includes the majority of GPCRs for peptide hormones, neurotransmitters, odorants, and a large group of orphans. Family 1 GPCRs can be divided by structural similarity into subfamilies: 1a that includes rhodopsin, adrenoceptors, thrombin, and the adenosine A_{2A} receptor, with a binding site localized within the 7-TM motif; 1b that includes receptors for peptides with the ligand-binding site in the extracellular loops, the N terminal, and the superior regions of the TM motifs; and 1c that comprises receptors for glycoproteins. Ligand binding to this receptor class is mostly extracellular. *Family 2* is morphologically related, but not sequence related to the 1c family and consists of four GPCRs activated by the hormones glucagon, secretin, and VIP-PACAP. *Family 3* contains four metabotropic glutamate receptors (mGluR) and three $GABA_B$ receptors. *Family 4* is a group of GPCRs that includes "frizzled" and "smoothened," both involved in embryonic development. Additional GPCRs have been described in invertebrate species that may define additional receptor families.

Interactions with heterotrimeric G-proteins and other associated signaling molecules have the potential for considerable complexity. Heterotrimeric G-proteins exist as complexes formed from α, β, and γ-type subunits, for each of which there are multiple subtypes, thereby offering a considerable variety of potential functional G-proteins. The α subunits are best characterized and often determine the signaling pathway activated There are four major G-protein α-subunit families that interact with GPCRs: (1) G_s that activates adenylyl cyclase; (2) $G_{i/o}$ that inhibits adenylyl cyclase and can also regulate ion channels and activation of cGMP PDE; (3) G_q that activates phospholipase C; and (4) G_{12} that regulates Na^+/H^+ exchange. The β and γ subunits are less well studied, but are also involved in signaling events such as interactions with ion channels and certain isoforms of phospholipase C, as well as in membrane trafficking and receptor interaction events.

10.1.1 G-protein–Associated or – Modulating Proteins

The cyclic nucleotide phosphodiesterases (PDEs) that are responsible for hydrolytic degradation of the cyclic nucleotides, cAMP and cGMP, exist in more than 15 isoforms. While the protein kinases, PKA and PKC, are responsible for protein phosphorylation, the GPCR kinases, GRK 1–6, are responsible for GPCR phosphorylation, and the protein phosphatases are responsible for dephosphorylation, the latter potentially numbering in excess of 300, significantly increasing the complexity of GPCR-associated signaling processes.

Superimposed on these signaling proteins are the calmodulins that mediate calcium modulation of receptor function, the β-arrestins, involved in inactivation of phosphorylated receptors (6 members), a group of proteins termed RGS (regulators of G-protein signaling), RAMPs, and a protein known as Sst2p that is involved in receptor desensitization.

Given the number of GPCRs present in the human genome, including orphan receptors, multiple G-protein subtypes, phosphatases, and the various GPCR-associated signaling proteins described earlier, there is obviously considerable scope for complexity in cell signaling associated with the GPCR family. GPCRs can also form homo- and heteromeric forms (e.g. $GABA_B$, adenosine A_1 and A_{2A}, angiotensin, bradykinin, chemokine, dopamine, metabotropic glutamate, muscarinic, opioid, serotonin, and somatostatin), further increasing the potential complexity of ligand-driven GPCR signaling processes and offering an opportunity to explore new targets in medicinal chemistry.

Applying an evolutionary trace method (ETM) to assess potential protein–protein interactions, Dean et al., identified functionally important residue clusters on TM helices 5 and 6 in over 700 aligned GPCR sequences. Similar clusters were found on TMs 2 and 3. TM 5 and 6 clusters were consistent with 5,6-contact and 5,6-domain swapped dimer formation. Additional application of ETM to 113 aligned G-protein sequences identified two functional sites: one associated with adenylyl cyclase, and regulator of G-protein signaling (RGS) binding, and the other extending from the ras-like to helical domain that seems to be associated with GPCR dimer binding. From such findings, it was concluded that GPCR dimerization and heterodimerization occur in all members of the GPCR superfamily and its subfamilies.

From these findings, potential new approaches to ligand design and by extrapolation, drug discovery, include: (1) antagonists that can act by inhibiting dimer formation, for example, transmembrane peptide mimics; (2) bivalent compounds/binary conjugates; and (3) compounds targeting the GPCR–G-protein interface.

10.2 Ligand-gated Ion Channels

Ion channels consist of homo- or heteromeric complexes numbering between three (P2X) and eight (Kirs) subunits. Examples of these are the $GABA_A$/benzodiazepine and NMDA/glycine receptor, neuronal nicotinic receptors (nAChR), and P2X receptors.

10.2.1 $GABA_A$/Benzodiazepine (BZ) Receptor

$GABA_A$/benzodiazepine receptor is an LGIC that is the target site for numerous clinically effective anxiolytic, anticonvulsant, muscle relaxant, and hypnotic drugs,

which produce their therapeutic effects by enhancing the actions of the inhibitory neurotransmitter, GABA. It is a pentameric LGIC, the constituent subunits of which are formed from a family of six, four, one, and two subunits, leading to the potential existence of several thousand different pentamers. The functional receptor complex contains a $GABA_A$ receptor, a BZ recognition site, and by virtue of its pentameric structure, a central chloride channel. Allosteric recognition sites on this complex include those for ethanol, avermectin, barbiturates, picrotoxin, and neurosteroids like allopregnanolone. The pharmacology and function of the allosteric sites depends on the actual subunit composition. The 1 subunit, which is present in nearly 60% of $GABA_A$ receptors, in mouse brain mediates the sedative, anticonvulsant, and amnestic effects of diazepam; the 2 subunit, the antianxiety effects of diazepam; and the 5 subunit, associative temporal memory. With this knowledge, rather than screening new ligands for the $GABA_A$ receptor in various animal models to derive a profile for a nonsedating anxiolytic, by understanding the structural determinants of BZ interactions with 1 and 2 subunits and designing compounds that preferentially interact with the latter, the process of designing novel ligands can be considerably enhanced.

10.2.2 The NMDA Receptor

The NMDA receptor is a member of the glutamate receptor superfamily that mediates the effects of the major excitatory transmitter, glutamate. It is composed of an NMDA receptor, a central ion channel that binds magnesium, the dissociative anesthetics, ketamine, and phencyclidine (PCP), the noncompetitive NMDA antagonist, dizocilpine (MK 801), glycine and polyamine binding sites, activation of which can markedly alter NMDA receptor function, and some 70 other ancillary proteins, the physiological function of which remains to be determined. The activation state of the receptor can define the effects of the allosteric modulators. Thus, some are termed *use-dependent*, reflecting modulatory actions only when the channel is opened by glutamate.

10.2.3 The Nicotinic Cholinergic Receptor, nAChR

The nicotinic cholinergic receptor is another pentameric LGIC composed of distinct functional regions and subunits. The subunit composition of the receptor varies, imparting different functionality when the channel is activated by nicotine, or by the endogenous ligand, ACh. Allosteric modulators of neuronal nAChRs include dizocilpine, avermectin, steroids, barbiturates, and ancillary proteins.

10.2.4 The P2X Receptor

The P2X receptor is an LGIC responsive to ATP that functions as a trimer formed from a family of seven subunits that can form both homo- and heteromers leading to the existence of at least seven distinct receptor subtypes.

Little is known regarding the structural elements involved in the ligand pharmacology and function of LGICs, such that signaling transduction pathways have not been extensively characterized. For nAChRs, it is known that the recognition site for ACh is formed between two subunits. Thus multiple orthosteric sites for ACh are possible, depending on the types of subunit forming the receptor. Many new classes of LGIC are still being discovered.

10.3 Steroid Receptor Superfamily

The steroid receptor superfamily includes the glucocorticoid (GR), progesterone (PR), mineralocorticoid (MR), androgen (AR), thyroid hormone (TR), and vitamin D_3 (VDR) receptors. These receptors bind steroid hormones and are then translocated to the nucleus, where they bind to hormone responsive elements on DNA promotor regions to alter gene expression. While steroids are very effective anti-inflammatory agents, they have a multiplicity of serious side effects that limit their full use.

The antiestrogen, tamoxifen, is the most commonly used hormonal therapy for breast cancer and has demonstrated positive effects on the cardiovascular and skeletal systems of postmenopausal women but is associated with an increased risk of uterine cancer. Tamoxifen is described as a selective estrogen receptor modulator (SERM) with a tissue selective profile dependent on the different distribution of the α- and β-subtypes of the estrogen receptor (ER-α and ER-β) that activate and inhibit transcription respectively. These selective effects have been ascribed to differential interactions with gene promotor elements and coregulatory proteins depending on whether the ER interacts directly, or in a tethered manner with DNA.

10.4 Intracellular Receptors

Members of the intracellular receptor family include the cytochrome P450 (CYP) family, the SMAD family of tumor suppressors, intracellular kinases and phosphatases, nitric oxide synthases (NOS), caspases, the RXR, RAR superfamilies, receptor activated transcription factors (RAFTs), and signal transducers and activators of transcription (STATs) such as AP-1, NFκB, NF-AT, STAT-1, PPARs, various hormone responsive elements on DNA and RNA promoters, and ribozymes. These represent a bewildering number of potential drug targets especially in the metabolic disease and cancer areas. Given their roles in normal cell function, it will be a challenge to ensure specificity in ligands interacting with these targets.

10.5 Non-GPCR-linked Cytokine Receptors

Cytokines are polypeptide mediators and are involved in the inflammatory/immune response. There are three cytokine families: *hematopoietin*, which includes IL-2–IL7, L-9–13; IL-15–IL-17; IL-19, 1L-21, IL-22, GMCSF, GCSF, EPO, LIF, OSM, and CNTF, with primary signal transduction through the Jak/STAT pathway; *tumor necrosis factor*, comprising the receptors, TNFRSF1–18 that signal through NFB, TRAF, and caspases; and the *interleukin 1/TIR* family that includes IL-1RI and IL-1RII, IL-1Rrp2, and IL1RAPL. TIGGR-1, ST2, IL-18, and Toll 1–9 also signal through NFB and TRAF.

10.6 Orphan Receptors

Orphan receptors have been generally defined as proteins with a receptor motif that lack both a ligand and function. Approximately 160–300 orphan GPCRs are thought to be in the draft sequence of the human genome and intense efforts are currently ongoing to identify the ligands for these and their function as novel intellectual property for the drug discovery process. Orphan receptor validation can be done using expression profiling to

identify tissues rich in the expression of the receptor of interest, and a technique known as *reverse pharmacology* that can be used to identify a ligand for the orphan receptor. In the latter, the orphan receptor is used as "bait" to bind selective ligands. These can then be used to further characterize receptor function. Nearly 30 orphan GPCRs have been validated in this manner. While most of the current interest on orphan receptors is focused on GPCRs because of the considerable body of existing knowledge about this receptor class, it is anticipated that orphan receptors will also be discovered for other receptor classes, for example, orphan nuclear receptors.

The orphan receptor approach to drug discovery is exemplified by the orphanin/FQ receptor, ORL1, a structural homolog of the opioid receptor. Identified in 1995 using a homology-based screening strategy, ORL1 had low affinity for known opioid ligands. A novel heptadecapeptide ligand for the ORL1 receptor, orphanin/FQ, was subsequently isolated from brain regions rich in ORL1 providing the key tool to validate the target and identify a functional role for the receptor in stress-related situations in animal models. From an intensive screening program, an antagonist of this receptor was identified, Ro 64–6198, which represented a novel anxiolytic/antidepressant drug candidate.

10.7 Neurotransmitter Transporters

Neurotransmitter transporters (NTs) are responsible for terminating the effects of neurotransmitters by removing them from the extracellular space. NTs are integral membrane proteins present on both the plasma membrane and on intracellular vesicles where they effect vesicular packaging of neurotransmitters. Their activity is dependent on the Na+ intracellular/extracellular gradient. Most NTs (e.g. dopamine transporters (DAT), norepinephrine transporters (NET), serotonin transporters (SERT) also require Cl^- and are termed *Na^+/Cl^- dependent NTs*, (SCDNTs) Transporters for glutamate also require K^+ (SKDGTs). These proteins bind their cognate neurotransmitters with high affinity and transport them across the plasma membrane into the cell. GABA transporters comprise the GAT family.

NT inhibitors represent a major class of drugs producing their effects by blocking neurotransmitter uptake, thus potentiating the actions of endogenous neurotransmitters. As such, NTs can be considered as indirect receptor agonists. Inhibitors of SERT (also known as *selective serotonin reuptake inhibitors*, SSRIs) are major antidepressants, for example, fluoxetine. Mixed SERT/NET inhibitors (SNRIs) are also antidepressants and analgesics while DAT inhibitors are well-known stimulants, e.g. cocaine, amphetamine and so on. Inhibitors of GABA transporter (GAT) are anticonvulsants (e.g. gabatril).

10.8 Neurotransmitter Binding Proteins

Binding proteins for corticotrophin releasing factor (CRF) and acetylcholine (AChBP) have been identified and exploited as potential drug discovery targets. These proteins can act as reservoirs or "decoy receptors" for their respective neurotransmitters, playing a general role in buffering synaptic message transfer.

10.9 Drug Receptors

Most drugs interact with receptors (or enzymes) for which the natural ligand

(or substrate) is known. There are, however, a number of receptors, distinct from the evolving class of orphan receptors, for which the synthesized drug is the only known ligand. The best example of this is the central benzodiazepine receptor present on the $GABA_A$ ion channel complex that was originally identified using radiolabeled diazepam. Because this is the site of action of the widely used BZ anxiolytic drug class, this is a *bona fide* receptor with clinical relevance. However, despite considerable efforts and a number of interesting candidate compounds, no endogenous ligand has yet been unambiguously identified which would represent an endogenous modulator of anxiety acting through this site. Other examples of drug receptors for which synthetic ligands were identified before the endogenous agonists, are the cannabinoid receptors, CB_1 and CB_2, through which the following compounds act: 9-Δ-tetrahydrocannibol, the active ingredient of the psychoactive recreational drug/analgesic/antiemetic drug, marijuana; the vanilloid receptor, VR-1, the known ligand for which is capsaicin, the ingredient in red pepper that evokes heat sensation; and the opioid receptor family, the site of action of morphine and other derivatives of the poppy. For each of these drug receptors, endogenous mammalian ligands, anandamide, the endovanilloid, *N*-arachidonyldopamine (NADA), enkephalins, and orphanin/FQ have been identified.

11
Molecular Biology of Receptors

Recombinant DNA methods have been extensively used to isolate and analyze the sequence of numerous receptors from various mammalian complementary DNA (cDNA) libraries using the polymerase chain reaction (PCR) technique to clone receptors that can then be expressed in various prokaryotic and eukaryotic cell lines and *Xenopus* oocyte. Conserved regions in receptors that are involved in ligand binding, coupling to transductional systems and ion channel formation, have thus been identified. Receptor cloning, sequencing, and expression are now an intimate part of the drug discovery process.

From the receptor/ligand modeling standpoint, the ability to specifically alter the structure of cloned receptors through the modification of a small number of nucleotides, the process known as *site-directed mutagenesis*, the removal of specific regions of the receptor gene ''deletion mutagenesis,'' and the construction of hybrid (chimeric) receptor proteins can provide additional clues on the relative importance of individual amino acids in the process of ligand recognition and receptor function. These techniques are also used to manipulate receptors to produce recombinant expression systems with better cell surface expression, more convenient signal transduction coupling, and other qualities important for efficient drug discovery.

12
Functional Genomics: Target Validation/Confidence Building

The identification of novel receptor targets from the human genome and their subsequent use in the drug discovery process requires that the target be validated. Their validation requires that the ligand and function of the receptor be known, and this topic has been addressed in relation to orphan receptors mentioned earlier.

Target validation, especially that related to novel, genomically derived targets, is

a highly complex and resource intense process, adding significantly to the cost of drug discovery. In addition to orphan receptors, identified on the basis of their homology to members of known receptor classes, novel genomic targets can be identified by drug-related differential gene expression analysis, population genetic approaches, or a combination of both. Once a gene is associated with a disease, its protein product needs to be characterized and a biochemical function, for example, receptor, enzyme, or transporter, ascribed to it. The probable function of the protein can then be assessed and its cognate ligand or substrate identified. Not all proteins identified in this manner are obviously involved in mammalian cell function. The protein product of a novel lithium-related (NLR) gene identified in mice exposed to lithium has sequence homology to a bacterial nitrogen permease. The potential role of this protein in the etiology of bipolar affective disorder remains unclear. Patients can also be genotyped for susceptibility related to a drug target or drug side effects, to identify ''responsive'' patients for more efficient and safer drug use.

To identify what are termed *druggable* gene products, the still somewhat mystical process of functional genomics can be used to construct protein–protein interaction maps, to identify other proteins in a pathway/network that can represent more facile entry points to the protein cluster associated with the genetically identified target and with the disease state. Using techniques like yeast two-hybrid and *gal*-pull down, the function of an uncharacterized protein can be assigned on the basis of the known function of its interacting partners, involving the extensive use of bioinformatics tools.

Targeted gene disruption, antisense, and ribozyme inhibition (RNAi) are other techniques for assessing the phenotype of a given gene. Antisense to the rat $P2X_3$ receptor had marked hyperalgesic activity showing an unambiguous role for this receptor in chronic inflammatory and neuropathic pain states. Transgenic animals, in which the function of a gene is knocked out by genetic techniques, are less useful in understanding the function of a protein. In addition to being restricted to the mouse, this approach is high in cost and time (taking 1–2 years to generate sufficient animals for evaluation), and in many instances, the absence of a given protein has no overt effect on the phenotype of an animal because of compensatory changes during the developmental phase. Alternatively, the gene knockout may lead to an animal that has a limited, if any, life span or reproductive capability.

Another target validation approach involves the use of ligands to define the function of a new target. Already discussed in regard to orphan receptors, other ligand-directed target validation models fall under the rubric of *chemical genomics*. A key to identifying useful ligands that selectively interact with proteins of unknown function to define their function is a sufficient level of pharmacophore diversity to ensure success.

Assuming that a novel protein target is amenable to HTS approaches to identify its cognate ligand, that the ligand is identified, and that other approaches are able to define a putative function for the target, the next step in target validation is to identify a ''druggable'' molecule that can be advanced to the clinic. For ORL1, Ro 64–6198 is an excellent example of this approach.

This raises the key test of *target validation* or *target confidence building*. Does a compound that has the appropriate potency, selectivity, and ADME properties, that is active in ''predictive'' animal models, and is free of other systems toxicology work in the targeted human disease state? This is the ultimate, and only, validation of a target-based drug discovery program. All events leading up to this point are more accurately defined as target confidence building. With the considerable compound attrition rates in moving from animals to diseased humans, this has not proven to be a predictable transition. A case in point is that of the NK1 receptor activated by the peptide, substance P.

Over the past decade, data from both animals and humans has implicated this receptor in a variety of human pain states including migraine and neuropathic pain. As the result of several successful HTS campaigns run in parallel at Pfizer, Lilly, Merck, and Sanofi Aventis, a number of highly efficacious and selective antagonists of the NK1 receptor were identified which were then chemically optimized for use as drug candidates. These compounds, with varying degrees of potency, were active in animal models of pain and were free of overt side effects in phase I human clinical trials. However, they uniformly failed in phase II studies as novel analgesic agents in patients with various pain conditions.

The reasons for this remain unknown and have focused on the relevance of animal pain models to the human condition, for example, a lack of understanding of the true human disease condition and various nuances of substance P signaling pathways. However, before the results with NK1 antagonists, drug discovery in the analgesia area was considered one of the most robust. All known analgesics, for example, aspirin and morphine, were active in one or more of the animal pain models; new receptors could be mapped in pain pathways and their function assessed using knockout and antisense procedures, and the occupancy of receptors in human brain and pain-sensing pathways could be noninvasively imaged. The only limitation was whether the side effect profile of a putative analgesic agent acting on a novel target or suboptimal ADME characteristics would limit human exposure.

On the basis of the available data, the NK1 receptor has not been validated as a target for pain treatment despite an overwhelming body of robust preclinical data. This example thus serves to underline the many significant challenges of validating targets in the drug discovery process at the present time.

A second example, more directly related to the human genome, is the search for genes that are associated, and by inference may be causative, in producing the psychiatric disorder schizophrenia. This disease affects nearly 1% of the population and has a strong genetic association. From studies comparing schizophrenic patients with individuals lacking symptoms of the disorder, LOD scores of 2.4–6.5 on markers between or close to markers D1S1653 and D1S1679 on chromosome 1q have been reported. An LOD score of above a numerical value of 3 is considered to be indicative of a relevant association akin to a significant P value ($P < 0.05$). With this information, a search for the gene on chromosome 1q and the delineation of its function in humans would be a logical approach to finding novel genomic targets that could lead to new drugs that would more effectively and safely treat schizophrenia. However, a subsequent study using eight individually collected schizophrenia populations and a sample set that was ''100% powered to detect a large genetic effect under the

reported recessive model,'' showed no evidence for a linkage between chromosome 1q and schizophrenia; a finding that could not be ascribed to ethnicity, statistical approach, or population size. Another group using two prefrontal cortex tissues from two separate schizophrenic populations showed an upregulation of apolipoprotein L1 gene expression that was not seen in tissue from patients with bipolar disorder or depression. The genes related to apolipoprotein L1 gene expression are clustered on the chromosome locus 22q12, providing another target for the functional genomic approach to target discovery and validation. Another locus at chromosome 3q has been reported.

To the researcher embarking on a well-funded, science-driven approach to new targets for schizophrenia in 1997, these new findings in 2002, as well as others showing gene association with schizophrenia on chromosomes 6 and 13, would give pause to wonder how best to proceed. Do all five locations represent *bona fide* targets for functional genomics? Should one continue work on the original chromosome 1 findings in light of the failure to replicate? Is the only real validation, in light of conflicting findings, to proceed to the identification of multiple compounds that can be tested in schizophrenic populations – to validate the genome-based approach? Given that the cost of initiating a project, finding leads, optimizing these, and running a single clinical candidate to phase IIa clinical proof of principle is in the range of $24–28 million, how many organizations can afford the $120 million+ cost to undertake scientifically logical yet financially prohibitive strategies? These are difficult questions that can be applied to many other psychiatric and neurological diseases, as well as to any other disease state with a potential genetic causality. One answer to these questions obviously points to multifactorial genetic causes in the genesis of many diseases and thus negates the overly simplistic ''one gene, one disease'' mantra that heralded the age of drug discovery based on the human genome map. Strategies resulting from the answers to these questions also make the process of genome-based target and drug discovery a much more costly endeavor, with good evidence for two to three or more potential targets for each disease that need to be examined in parallel. Hopefully, the quality of the target finally validated using compounds in the human disease state will be a magnitude of order superior to currently existing drugs and will thus justify the cost of this approach.

13
Compound Properties

Once a target has been identified, the challenge then becomes the identification of compounds that selectively interact with the target and can be used as the basis of a lead optimization program to identify potential drug candidates.

An ideal compound should have the appropriately unique recognition characteristics to impart affinity and selectivity for its target, have the necessary efficacy to alter the assumed deficit in cell function associated with the targeted disease state, be bioavailable, metabolically, and chemically stable (drug like, be chirally pure, and be easy and cost-effective to synthesize).

13.1
Structure-activity Relationships

The structure-activity relationship (SAR) of a compound series is a means to relate changes in chemical diversity to the

biological activity of the compound *in vitro* and *in vivo*, as well as the pharmacokinetic (gut/blood brain barrier transit, liver metabolic stability, plasma protein binding, etc.) and toxicological properties of the molecule. These SARs, when known, are frequently distinct such that changes that improve the bioavailability of a compound often decrease its activity and/or selectivity. Compound optimization is thus a highly iterative and dynamic process.

For the purpose of the present review, SAR is used to describe classical compound efficacy unless otherwise stated. Quantitative SAR (QSAR) involves a more mathematical approach involving neural networks and computer-assisted design.

Following the characterization of the SAR and the documentation of the effects of different pharmacophores and various substituents on biological activity, it is possible to theoretically model the way in which the ligand interacts with its target and thus derive a two- or three-dimensional approximation of the active site of the receptor or enzyme. Computer-assisted molecular design (CAMD) techniques can then be used to predict – sometimes successfully – the key structural requirements for ligand binding, thus defining those regions of the receptor target that are necessary for ligand recognition and/or functional coupling to second messenger system to permit the design of new pharmacophores.

The SAR can be further delineated in terms of the type of activity measured as the readout. *In vitro*, this can be displacement of a radiolabeled ligand from a receptor, receptor activation as measured in a functional assay, blockade of receptor function by an antagonist ligand, and so on. An additional ligand property is that of selectivity, the degree to which a ligand interacts with the target of choice compared with related structural targets. The degree of selectivity typically determines the side effect profile of a new compound, given that the targeted mechanism itself does not produce untoward effects when stimulated beyond the therapeutic range. As noted, the development of a ligand binding profile for a ligand active at a new target is very useful in assessing its effects in more complex tissue systems.

13.2 Defining the Receptor–Ligand Interaction

The complex physiochemical interactions that describe the interaction of a small molecule with a protein, despite the many sophisticated technologies used to study this interaction, are still highly empirical, being implicitly defined by the SAR for a series of active and less active compounds. In an increasing number of instances, however, the ability to clone, express, and readily derive crystals of a receptor or enzyme and analyze the interaction of a ligand or substrate with these using X-ray crystallographic, NMR, and amino acid point mutation approaches, has provided information on the actual topography of the selected drug target that can then be used in *de novo* ligand design.

There are a variety of approaches to derive information on the RL interaction for use in understanding the key features required in ligand necessary to dictate a potent and selective interaction with its target. Analysis of the interactions of a series of structurally distinct pharmacophores, agonists, and antagonists with the target can be combined with point mutation changes in the target to elucidate key amino acids involved in compound recognition. This can be complemented by X-ray crystallographic and

NMR-derived data to design novel pharmacophores. However, many proteins of interest, especially membrane-bound receptors and ion channels, are not available in the soluble form amenable to the use of these techniques such that the design of new compounds is based on the conceptualization of the target, for example, virtual receptors. There are also limitations to structure-based design approaches, for example, approximations of the hydration state of the isolated protein, the impact of removal from its native environment, and three-dimensional structural issues with recombinantly derived proteins. Nonetheless, these technologies have been useful in compound design. More recently, automated, high-throughput approaches have been applied to X-ray crystallography, providing a more rapid means to generate information on multiple ligand interactions with a given crystal.

13.2.1 Receptor-binding Assays

Until the 1960s, newly synthesized compounds and compounds isolated from natural sources were assessed by a mixture of *in vivo*, whole animal screens, and classical tissue assays. While many useful therapeutic agents were identified by this approach, the cost, in terms of compound quantity as well as time and animal use was considerable. *In vivo* test paradigms also suffered from the possible elimination of interesting compounds on the basis of unknown pharmacokinetic properties as test paradigms were usually routine in terms of timing, and as a result, many potentially interesting compounds that exhibited short plasma half-lives were considered ''inactive'' because data on their actions was sought after their peak plasma concentration. This type of screening approach also provided little useful chemical information about discrete interaction of the drug with its target, limiting the design of analogs. The specificity of the response, ignoring caveats related to pharmacokinetics, was not ideal because the mechanism inducing the overt response and potential points of intervention to block the response were unknown.

This empirical approach would predict, in the absence of any data related to specific interactions with a molecular target, that because β-adrenoceptor antagonists lower blood pressure, then any compound that lowers blood pressure is by definition a β-adrenoceptor antagonist. The 1970s saw the development of a number of *in vitro* biochemical screens that moved the measurement of the RL interaction a little closer to the molecular level. Nonetheless, the major challenge was to develop assays that measured the RL interaction independently of ''downstream'' events such as enzyme activation and second and third messenger systems. By such means, the ability of a compound to bind to a receptor could be determined on the basis of the SAR and thus provide the chemist with a more direct means to model the RL interaction.

Snyder, building on pioneering work by Roth, Cuatrecasas, and Rang developed radioligand binding as a valuable tool in the drug discovery process in 1973. This led to an explosion in the identification and characterization of new receptors and their subtypes, which was enhanced by the application of tools of recombinant DNA technology to the process.

While the technique of radioligand binding has been largely supplanted by activity-based assays in many high-throughput settings, it remains the gold standard for compound characterization and SAR development. It is done by measuring the RL interaction (Equation 1) *in vitro* using a radioactive ligand, R*, to bind with high

affinity and selectivity to receptor sites. The interaction of unlabeled (''cold'') ligands with the receptor competes with the radioligand, decreasing its binding. This simple technique revolutionized compound evaluation in the 1970s, allowing SARs to be determined with milligram amounts of compound in a highly cost- and resource-effective manner. At steady state, the RL* complex can either be separated out from free radioligand using filtration or assayed using a scintillation proximity assay.

The parameters measured in a binding assay are the dissociation constant, K_d, the reciprocal of the affinity constant, K_a. The K_d is a measure of the affinity of a radioligand for the target site: the B_{max}, usually measured in moles per milligram protein, a measure of the concentration of binding sites in a given tissue source and the IC_{50} value. The K_d and B_{max} values can be determined using a saturation curve where the concentration of radioligand is increased until all the ligand recognition sites are occupied, or by measuring radioligand association and dissociation kinetics; K_d is the ratio of the dissociation and association rate constants.

The IC_{50} value is the concentration of unlabeled ligand required to inhibit 50% of the specific binding of the radioligand. This value is determined by running a competition curve (Fig. 5) with a fixed concentration of radioligand and tissue, and varying concentrations of the unlabeled ligand. To accurately determine the IC_{50}, it is essential that sufficient data points be included. As shown in Fig. 5, if the data used to derive the IC_{50} value are clustered over a range that reflects 40 to 60% of the competition curve, much useful information is lost. Ideally, the competition curve should encompass the range of 10 to 90% of the competition curve and include a minimum of 20 data points. On the basis of Michaelis–Menten kinetics, when binding is the result of the interaction of the displacer with one recognition site, 10 to 90% of the radioligand is inhibited over an 82-fold concentration range of the displacer. The slope of a competition curve can then be analyzed to assess the potential cooperation of the RL interactions. When binding is complex resulting in the interaction of the displacer with more than one recognition site, a greater than 82-fold concentration of displacer is required to inhibit the same 10 to 90% of specific radioligand binding.

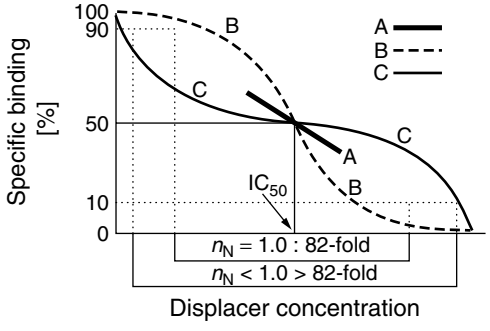

Fig. 5 Measuring ligand interactions in a receptor-binding assay. Binding of the radioligand is 100%. In curve A, close to the 50% point, an IC_{50} value can be obtained but ignores complexities of the displacement curve. More complete displacement, as in curves B and C, provides more information on the ligand. Displacement curve B has a Hill coefficient of unity requiring an 82-fold difference in displacer concentration to displace 10 to 90% of binding. Displacement curve C has a Hill coefficient of less than one, requiring a greater than 82-fold difference in displacer concentration to displace 10 to 90% of binding, and indicating the presence of more than one site. By extending the range of concentrations used, curves B and C can assess the possibility of multiple sites being present.

The IC_{50} value for a given compound is dependent on the assay conditions: the concentration of the radioligand used, the receptor density, and the affinity of the receptor, the K_d, for the radioligand. To compare the activity of a "cold" ligand across different radioligand binding assays, the Cheng–Prusoff equation is used to compensate for differences in K_d and the radioligand concentration to obtain a K_i value derived by the relationship:

$$K_i = \frac{IC_{50}}{1} + \frac{[L]}{K_d} \quad (5)$$

where [L] is the concentration of radioligand used and K_d is the dissociation constant for the radioligand at the receptor. This relationship thus corrects for inherent differences in assay conditions.

Binding assays can be rapidly used to assess compound recognition characteristics but are generally limited in their ability to delineate agonists from antagonists, especially in a high-throughput setting.

13.2.2 Functional Assays

Biochemical assays involving the measurement of cAMP production or phosphatidylinositol turnover have given way in HTS scenarios to reporter systems in which receptor activation or inhibition can be measured using a fluorescence-based readout. This depends on the use of calcium sensing dyes coupled with real-time measurement using charge coupled device (CCD) cameras and data capture. While many types of plate reader are available, a widely used system is the fluorescence imaging plate reader (FLIPR). Using a 96- or 384-well microtiter plate format, the throughput on an FLIPR is such that compound libraries of 0.5 million distinct compounds can be assayed in weeks.

Other approaches to functional assay include various reporter gene constructs in which formation of the RL complex leads to the expression of a gene that produces a response that can be read immediately. These include various luciferase reporter gene or aequorin-based assays that produce light that can be measured by multiple photodiode arrays, and α-galactosidase reporter gene that leads to a colorimetric readout. Frog melanocytes transfected with GPCR cDNA represent yet another approach to determining whether a ligand is an agonist or antagonist that is independent of a reporter gene construct. Addition of melatonin to a transfected oocyte reduces intracellular cAMP concentrations resulting in the aggregation of the pigment in the cells. Agonist stimulation of the transfected cell increases cAMP resulting in pigment dispersal, a reaction that can not only be immediately determined visually on a plus/minus basis but can also be quantified in terms of light transmission.

The ability to measure colocalization of two cellular components in living cells is an increasingly powerful technique in understanding ligand–receptor and protein–protein interactions. Two such approaches are fluorescence resonance energy transfer (FRET) that measures the proximity of two proteins through the use of a luciferase tag on one partner and green fluorescent protein (GFP) on the other, and fluorescence polarization (FP) that relies on a polarized excitation light source to illuminate a binding reaction mixture. The smaller partner (e.g. the ligand) must be fluorescently labeled, and if this is unbound then it will, by tumbling in solution, emit depolarized fluorescence. This is thus a means of looking at the amount of unbound ligand in the binding mixture and has the

benefit of not requiring any washing steps. Current systems do not work well with turbid solutions or fluorescent compounds, although the latter has largely been dealt with through the use of red fluorescent dyes.

13.3 Receptor Sources

The choice of a tissue or cell line as a receptor source has a significant impact on the data generated. The natural receptor concentration in most tissues is in the femtomole to picomole range; brain tissue has a much higher density of receptors because of more extensive nerve innervation. Expression of the drug target in a cell line can, however, lead to differences in the number of receptors expressed per clone, a factor dependent on the relative proportion of transient to stable expressed cells and the passage number of the transfectants. Thus, the number of receptors can vary, affecting the apparent activity of unknown ligands that compete for binding with the radioligand.

As the drug targets of greatest interest are those in the human, the use of a human receptor or enzyme would seem ideal in defining the SAR of a potential drug series. The drawback, however, is that nearly all the toxicology and safety studies done in preparing a compound for clinical trials are conducted in rodents, dogs, and nonhuman primates. If there are no species differences between rat and human, this testing becomes a moot point. If on the other hand, the human target is substantially different from that in rat or dog or monkey, and there are many examples of this, the safety and toxicology studies may be conducted on a compound that has limited interactions with the drug target in species other than human. One approach is to incorporate human receptor orthologs into mice.

The use of transfected cell lines in compound evaluation can lead to a number of potential artifacts. Activation of transfected receptor may result in an increase in cAMP, a second messenger effect that may already be known to be a consequence of ligand activation of the receptor in its natural state. It is also possible that the transfected receptor may activate a cell-signaling pathway in the transfected cell that is not linked to the receptor in its normal tissue environment. In this instance, the second messenger readout actually functions as a ''reporter,'' a G-protein–linked phenomenon that results from the introduction of the cDNA for a GPCR and the generic or promiscuous interaction of the receptor with the G-protein systems. The introduction of the cDNA for any GPCR may then act to elicit a similar response. It is then advisable to use caution in extrapolating events occurring in the transfected cell to the physiological milieu of the intact tissue, and there is at least one case in which a compound identified as an antagonist in a cell system overexpressing the receptor of interest was subsequently found to be a partial agonist after it exacerbated disease symptomatology in phase II clinical trials.

13.4 ADME

In evaluating new compounds, it is only in the past 15 years that the ability of a compound to reach its putative site of action has been a priority in the discovery phase of compound identification. For many years, it was naively assumed that there was a generic approach that could be used on compounds with poor bioavailability that would turn them into

drug candidates. With attrition rates of lead compounds in the clinical development process of 50 to 60% range, with one estimate of greater than 90%, this was clearly not the case. Hodgson has noted, ''a chemical cannot be a drug, no matter how active nor how specific its action, unless it is also taken appropriately into the body (absorption), distributed to the right parts of the body, metabolized in a way that does not instantly remove its activity and eliminated in a suitable manner – a drug must get in, move about, hang around and then get out.'' The factors involved in defining *in vivo* activity form the basis of Lipinski's ''Rule of 5.'' In this widely cited, retrospective study, a number of compounds have been assessed and used to design new molecules. The physical properties that were determined as limiting bioavailability were as follows: molecular weight greater than 500; more than 5 hydrogen bond donors; more than 10 hydrogen bond acceptors; and a *C* log *P* value less than 5.

A retrospective evaluation of the oral bioavailability of 1100 novel drug candidates with an average molecular weight of 480 from SmithKline Beecham's drug discovery efforts in rats by Veber established that reduced molecular flexibility, measured by the number of rotatable bonds and low polar surface area or total hydrogen bond count (sum of acceptors and donors), were important predictors of good (>20–40%) oral bioavailability, independent of molecular weight. A molecular weight cutoff of 500 did not significantly separate compounds with acceptable oral bioavailability from those with poor oral bioavailability, the predictive value of molecular weight was more correlated with molecular flexibility than molecular weight *per se*. From this retrospective analysis, Veber et al. suggested that compounds with 10 or fewer rotatable bonds and a polar surface area equal to or less than 140 A^2 (representing 12 or fewer H-bond acceptors and donors) have a high probability of having good oral bioavailability in rats. Reduced polar surface area was a better predictor of artificial membrane permeation than lipophilicity (*C* log *P*), with increased rotatable bond count having a negative effect on permeation and having no correlation with *in vivo* clearance.

ADME is now a routine part of the efforts of a drug discovery team with the use of a number of *in vitro* approaches, for example, Caco 2 intestinal cell lines, human liver slices, or homogenates to assess potential metabolic pathways, in addition to classical rat, dog, and nonhuman primate *in vivo* studies, none of which has yet shown reliable predictability for the human situation. More recently, proteomic approaches have been used to derive potential toxicological profiles.

13.5 Compound Databases

With the exponential increase in information flow resulting from the ability to make many more compounds and test these in multiple assays, the capture, analysis, and management of data is a critical success factor in drug discovery.

Many databases used in drug discovery are ISIS/Oracle-based using MDL structural software and a variety of data entry and analysis systems, some are PC/Mac-based, and some are on a server. The ability to capture data and then reassess its value through *in silico* approaches has the potential to be a vast improvement over the ''individual memory'' systems that many drug companies used for the better part of the last century. Thus, with the retirement of a key scientist, the whole history

of a project or even a department disappeared, and whatever folklore existed regarding unexplained findings with compounds 10 or 20 years before was lost with the individual.

14 Lead Compound Discovery

As evidenced by the compound code numbers used by pharmaceutical companies, many thousands of new chemical entities have been made since the industry began in the late nineteenth century. Until the advent of combinatorial chemistry, the chemical libraries at most of the major pharmaceutical companies numbered from 50 000 to 800 000 compounds and comprised of newly synthesized compounds as well as those from fermentation and natural product sources. Approximately 2 to 5 million compounds were identified in the search for new drugs to treat human disease states over the past century. This number has obviously leaped to the billions with combinatorial approaches. Given decomposition and/or depletion of compounds, the 2 to 5 million compounds could be rounded down to 1 million.

The 2001 edition of the *Merck Index*, the compendium of drugs and research tools, lists a total of 10 250 compounds. Thus, from a hypothetical million compounds, only 1% has proven to be of sustained interest as either therapeutic agents or research tools.

In the early 1980s, with the promise that compounds could be created and tested on a computer screen (a promise as yet unrealized), the screening of large numbers of compounds against selected targets in biological systems was viewed as irrational. Indeed, the head of research at one of the top 20 pharmaceutical companies told the medicinal chemists at that company in the early 1980s that the demand for their skills was becoming less and would cease by the 1990s, a viewpoint somewhat akin to the apocryphal story of the head of the US Patent Office in the early 1900s who recommended its closure because "everything that could be discovered had been discovered."

The breakthrough for screening came in 1984 with the identification by Chang and colleagues at Merck of the CCK antagonist, asperlicin, which led to the clinical candidate, MK 329. Considerable effort has been expended in the pharmaceutical industry worldwide to capitalize on this approach, with significant successes, which have enhanced the search for novel chemical entities as well as providing research tools to better understand receptor and enzyme function.

14.1 High-throughput Screening

To identify compounds, it is imperative that a rapid, economical, and information-rich evaluation of biological activities be available. The term high-throughput screening describes a set of techniques designed to permit rapid and automated (robotic) analysis of a library of compounds in a battery of assays that generate specific receptor- or enzyme-based signals. These signals may be membrane-based (radioligand binding, enzyme catalysis) or cell-based (flux, fluorescence). The primary purpose of HTS is not to identify candidate drugs, but rather to identify lead structures, preferably containing novel chemical features, which may serve as a guide for more tailored iterative optimization. HTS should generate as few false-positive leads as possible because exploitation of

leads is an expensive component of the drug discovery process. HTS is designed to give information principally about potency, and a combination of follow-up screens may provide information about selectivity and specificity. The increasing use of cell-based assays provides additional information, including agonist/antagonist characteristics, and a biological ''readout'' under physiological or nearly physiological conditions. Additionally, cell-based assays can provide information about the cytotoxicity and bioavailability of molecules. The increased use of ''designer cells'' with visual and fluorescent signal readouts will continue to facilitate the screening process, and in the future, will doubtlessly include measures of metabolism, toxicity, bioavailability, and other important pharmacokinetic parameters.

Using FLIPR-like instrumentation, 100 000 or more compounds can be screened through 10 to 20 targeted assays in less than a week, and complete libraries numbering in the millions can be assessed at single concentration points in about a month. The issue is the success rate, typically in the 0.1% range, and the ability to capture and store the data for posterity. Clearly, the quality and diversity of the compounds and the robustness of the assays play a key role in a successful screening program.

14.2 Compound Sources

New chemical entities (NCEs) are discovered or developed/optimized from the following: (1) natural products and biodiversity screening; (2) exploitation of known pharmacophores; (3) rationally planned approaches, for example, computer-assisted molecular design; (4) combinatorial or focused library chemistry approaches; and (5) evolutionary chemistry.

14.2.1 Natural Product Sources

Approximately 70% of the drugs currently in human use originate from natural sources including morphine, pilocarpine, physostigmine, theophylline, cocaine, digoxin, salicylic acid, reserpine, and many antibiotics. Medicinal and herbal extracts form the basis for the health care of approximately 80% of the world's population; some 21 000 plant species are used worldwide. Screening of natural products led to the discovery of the immunosuppressants, cyclosporin, rapamycin, and FK 506, and there is a continued search for new compounds, even in relatively well-explored areas such as China.

The continued destruction of habitat with the accompanying loss of animal and plant species may impede further natural product-based drug discovery. Many interesting drugs have vanished. For example, a plant called *silphion* by the Greeks and sylphium by the Romans grew around Cyrene in North Africa. It may have been an extremely effective antifertility drug in the ancient world but was harvested to extinction.

While 100% of the world's mammals are known, fewer than 1 to 5% of other species, bacteria, viruses, fungi, and most invertebrates, are well characterized. It has been estimated that only 0.00002 to 0.003% of the world's estimated 3 to 500×10^6 species are used as a source of modern drugs. Exploration of environments previously assumed to be hostile to life has revealed bacterial species living at extreme depths, at extraordinary temperatures, and in the presence of high concentrations of heavy metals.

The sea covers almost three-quarters of the earth's surface and contains a broader

genetic variation among species relative to the terrestrial environment. Although a number of important molecules have been derived from marine sources, including arabinosyl nucleotides, didemnin B, and bryostatin 1, there has been an inadequate focus on this potentially chemically productive biosphere. Sea snails, termed *nature's combinatorial chemistry factories*, produce a bewildering array of novel conotoxins active as mammalian drug targets. These toxins are typically 10–30 amino acid residues in length, contain several disulfide bridges, and are rigid in structure. There are several hundred varieties of cone snails, and each may secrete more than 100 toxins. Therefore, there are likely to be several tens of thousands of these toxins, representing a library of substantial structural and functional diversity. These peptides are first synthesized as larger precursors from which the mature peptide is cleaved. In the mature peptide, there is a constant N terminus region and a hypervariable C terminus region from which the biological diversity is derived. Conus toxins have proven to be invaluable as molecular probes for a variety of ion channels and neuronal receptors and as templates for drug design.

Poison frogs of the *Dendrobatidae* family contain a wide variety of skin-localized poisonous alkaloids that are presumably secreted for defensive purposes. Among the chemical structures present are the batrachotoxins, pumiliotoxins, histrionicotoxins, gephyrotoxins, and decahydroquinolines (Fig. 6) that target both voltage- and ligand-gated ion channels. The alkaloid epibatidine (Fig. 6), present in trace amounts in *Epipedobates tricolor*, is of particular interest because it has powerful analgesic activities, being 200 times more potent than morphine. The alkaloid is a potent neuronal nicotinic channel agonist selective for the $\alpha 4\beta 2$ subtype. Isolated by Daly and Myers in 1974, the structure of epibatidine was not determined until 1992. The discovery of epibatidine as a novel and potent analgesic led to the identification of ABT-594, which had equivalent analgesic efficacy to epibatidine but with reduced side effect liabilities. Despite continued successes in isolating new compounds with pharmaceutical potential from natural sources, the pharmaceutical

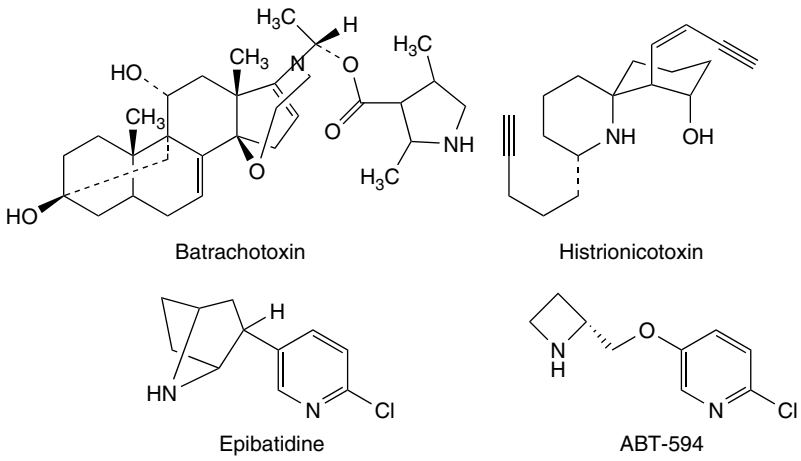

Fig. 6 Alkaloids and related structures.

industry has tended to loose interest in this approach limiting an important aspect of chemical diversity.

14.2.2 Pharmacophore-based Ligand Libraries

The majority of pharmaceutical companies have relatively large chemical libraries representing the cumulative synthetic efforts of the medicinal chemists within the company. Typically, the chemical diversity in these libraries is limited as the synthetic approach to drug design revolves around defined pharmacophores in lead series and the rational and systematic development of the SAR. Companies will thus have a large number of similar compounds based on the approaches and successes attendant to a therapeutic area.

The systematic modification of existing structures, both natural and synthetic, is an approach to compound optimization with improvements in potency, selectivity, efficacy, and pharmacokinetics being linked to discrete changes in molecular constituents on the basic pharmacophore.

Angiotensin-converting enzyme (ACE) inhibitors are important cardiovascular drugs that block the conversion of angiotensin I, formed by the action of renin on substrate angiotensinogen, to angiotensin II (a powerful pressor and growth factor agent). Until 1973, peptide inhibitors from the venom of the Brazilian viper were the only known inhibitors of this enzyme. The nonapeptide, teprotide, was an orally active and competitive inhibitor of ACE. Benzylsuccinic acid, a potent inhibitor of carboxypeptidase A, an enzyme with structural and mechanistic similarities to ACE, led Ondetti to select *N*-succinyl-l-proline as a lead ($IC_{50} = 330$ p*M*). This was subsequently optimized on the basis of the presence of a Zn^{2+} in the active site of both ACE and carboxypeptidase and the likely presence of hydrophobic pockets. An SH group to coordinate Zn^{2+} was incorporated into the stereoselectively active methyl analog, which eventually led to captopril and the analogs, enalapril, cilazapril, and lisinopril (Fig. 7).

14.2.2.1 **Molecular modeling.** Rationally planned approaches to structure design are an increasingly important part of the drug discovery process, whether planned *ab initio*, derived from structural knowledge of a putative ligand-binding site on a biological target in the absence of ligand information, or derived by rational exploitation of an existing chemical lead.

14.2.2.2 **Privileged pharmacophores.** It is increasingly apparent that a small number of common structures – ''basic pharmacophores,'' ''templates,'' or ''scaffolds'' – are associated with a multiplicity of diverse biological activities. These structures represent facile starting points for combinatorial chemical approaches to ligand diversity.

Benzodiazepines The benzodiazepines are well established as anxiolytics, hypnotics, and muscle relaxants as represented by diazepam, clonazepam, midazolam, and triazolam (Fig. 8). The BZ nucleus also occurs in natural products. Asperlicin is a naturally occurring ligand that is a weak, albeit selective, antagonist at cholecystokinin receptors and contains a benzodiazepine nucleus. From this lead was derived a series of potent and selective benzodiazepine ligands, active at CCK_1 and CCK_2 receptors, for example, L-364 718. Other BZs (Fig. 8) with activity at receptors distinct from the BZ receptor are as follows: tifluadom (opioid receptor);

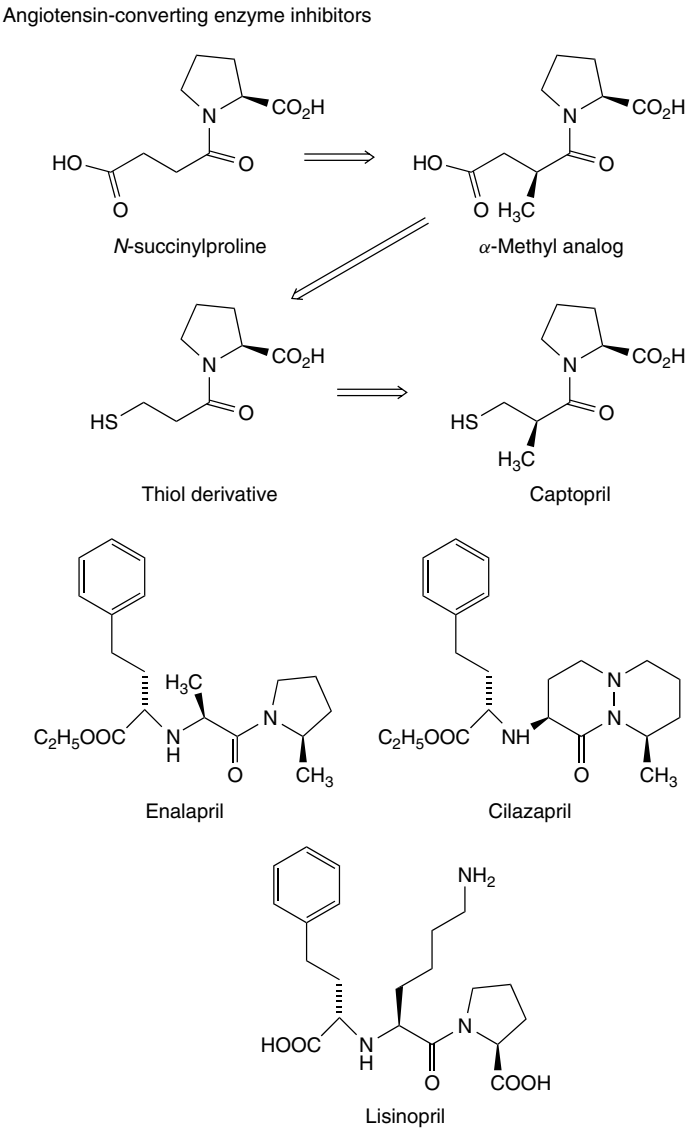

Fig. 7 ACE Inhibitors.

somatostatin; GYKI 52466 (glutamate receptor); and inward-rectifying potassium channels.

1,4-Dihydropyridines(DHP) The DHP pharmacophore is a well-established chemical entity. Nifedipine (Fig. 9) and several related DHPs, including amlodipine, felodipine, nicardipine, nimodipine, and nisoldipine, are well-established antihypertensive and vasodilating agents that act through voltage-gated L-type Ca^{2+} channels in the vasculature. However, DHPs also interact with lower activity at

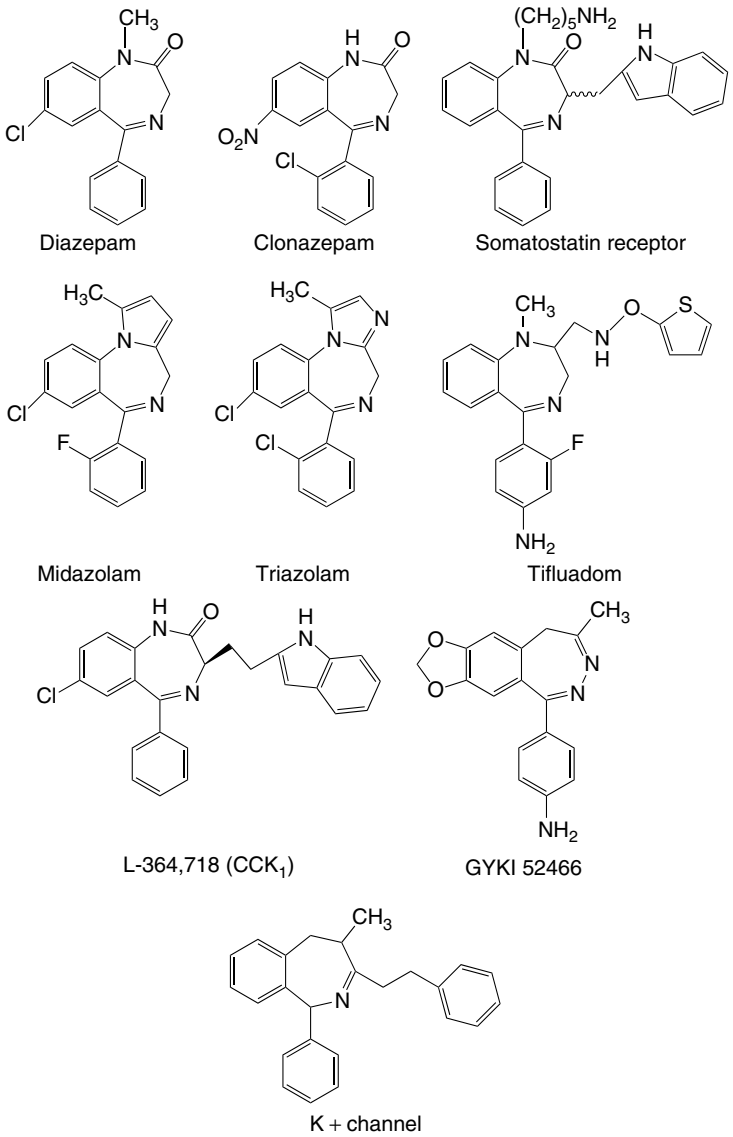

Fig. 8 Benzodiazepines: anxiolytics, hypnotics, and compounds with activity at other targets.

other classes of Ca^{2+} channels, including N- and T-type channels, and ''leak'' channels. DHPs can block delayed rectifier K^+ channels and cardiac Na^+ channels. Other DHP analogs (Fig. 9) are active at PAF receptors (UK 74,505), adenosine A_3 receptors, K^+ ATP channels (ZM 24 405 and A-278 367), capacitative SOC channels (MRS 1845), and α_{1A}-adrenoceptors (SNAP 5089).

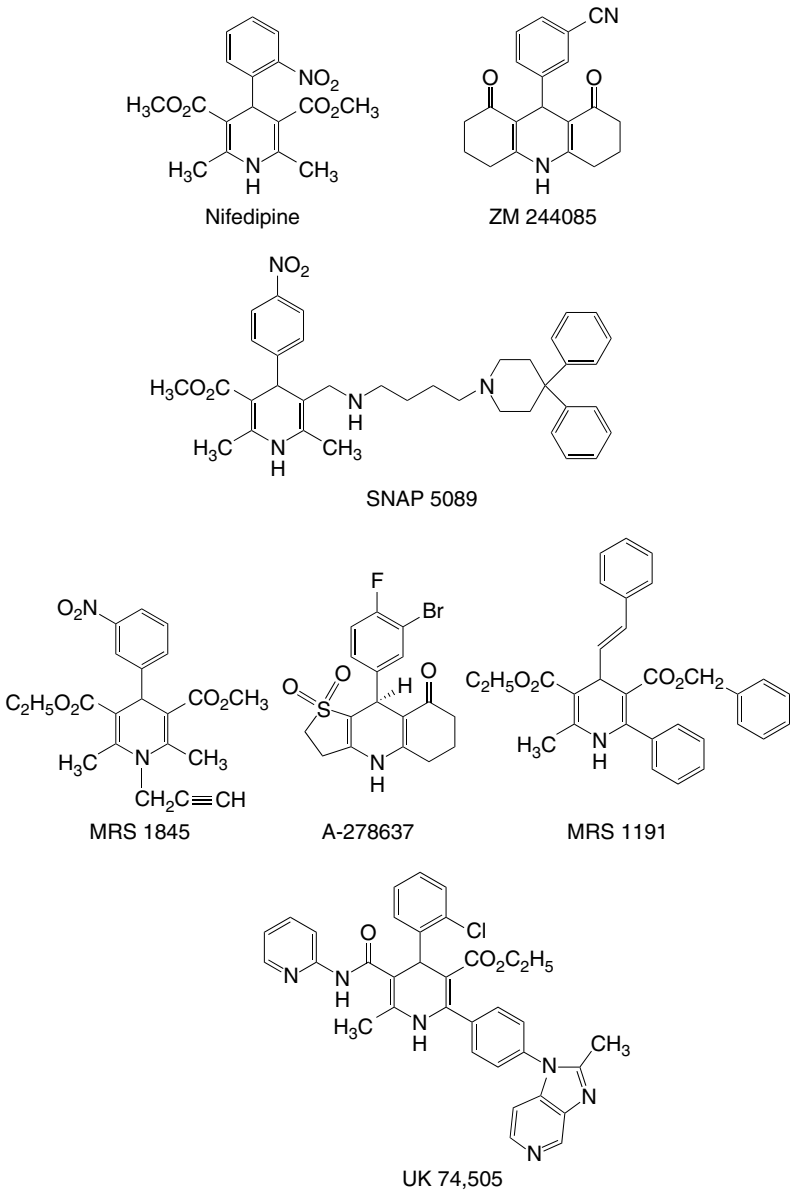

Fig. 9 Dihydropyridines; calcium channel, and other receptor antagonists.

14.2.3 **Diversity-based Ligand Libraries**

The issue of diversity reflects the need to enhance the scope of the library beyond those available within a company. This can be done by compound exchange with other companies, by acquiring compounds from university departments and commercial sources (Sigma, Asinex, Bader, Maybew, Cookson, etc.). Additional sources of novel synthetic compounds include

the libraries of major present or former chemical/agricultural companies and their successors like Eastman Kodak, Stauffer, FMC, and Shell, and chemicals made in the former Eastern Block countries that are now being brokered to pharmaceutical companies. In conjunction with the use of computerized cluster programs, the selection of compounds based on diverse structures can be considerably enhanced to provide maximum coverage of molecular space. This can be done by generating libraries of approximately 2000 compounds that is used to rapidly identify potential leads for a new drug target using the SAR generated in an HTS assay. Such libraries are assembled from compounds that are available in relatively large supply and may not necessarily be proprietary to the company. Their value is in rapidly eliminating unlikely structures in a systematic manner for each new target.

Combinatorial chemistry has provided the means to synthesize literally billions of molecules, a major step forward in the exploration of ''molecular space.'' This random or ''brute-force'' approach to the search for new leads has been a major disappointment in its contribution to product pipelines and the sacrifice of quality for quantity. However, combinatorial exploration around lead compounds or pharmacophores to generate dedicated libraries, when coupled with HTS, clearly provides an economical and efficient way to rapidly generate lead compounds.

Combinatorial diversity can be exploited in nature in the repertoire of antibodies with their remarkable combination of high affinity and selectivity and is also reflected in the conotoxins.

The polyketides are a family of natural products containing many important pharmaceutical agents that are synthesized through the multienzyme complex, polyketide synthase, which can display substantial molecular diversity with respect to chain length, monomer incorporation, reduction of keto groups, and stereochemistry at chiral centers. This variability, together with the existence of several discrete forms of polyketide synthase, allows the generation of diverse structures like erythromycin, avermectin, and rapamycin. This biochemical diversity has been considerably expanded by the introduction of new substrate species that were used by the enzymes to produce new or unnatural polyketides.

These methods are likely to be more extensively used in the future to provide a highly focused combinatorial approach to generating molecular diversity. The multienzyme pathway responsible for converting simple linear unsaturated allylic alcohols to sterols, carotenoids, and terpenes is incompletely characterized, but offers excellent potential for genetic manipulation to provide directed biocombinatorial chemistry.

14.3 Biologicals and Antisense

The use of the naturally occurring hormones as drugs is not new as evidenced by the use of insulin and epinephrine. The techniques of molecular biology allow the production of an increasing number of native and modified hormones and their soluble forms. Erythropoietin (EPO) is a classic example of a successful drug taken from the human body. Soluble receptors like Enbrel and humanized antibodies, for example, herceptin and D2E7 (Humira), are additional examples of how cloning techniques have altered the concept of rational drug design and what can be considered as a drug. Anticytokine therapies are particularly amenable to this approach.

Antisense oligonucleotides and RNA interference (RNAi) approaches may similarly provide novel, specific to disease treatment by the suppression/modification of a gene product. The fundamental concept is that an oligonucleotide, complementary to a disease-causing gene will anneal to that gene and prevent its transcription. In a similar manner, RNAi approaches use the fact that double-stranded RNA is rapidly degraded, and double-stranded RNA oligomers can trigger degradation of the genes encoded by them. While delivery issues remain a concern, one topically active antisense drug, Vitravene (ISIS) is approved for the treatment of CMV-induced retinitis.

15 Future Directions

The gradual evolution of the receptor concept as the basis for drug discovery over the past century has led to major advances in the understanding of biological systems and human disease states.

While the development of ever more sophisticated structure-based technologies and ultra, micro-HTS that encompass activity, ADME, toxicity, and structural data generation has resulted in an ever-increasing body of knowledge, it does not seem to have added significantly to success as measured by increased numbers of quality INDs (investigative new drug applications), but rather, together with genomics and proteomics, significantly added to the cost of the search for new medicines. The medicinal chemist and the pharmacologist play key roles in integrating and interpreting the data flow that constitutes much of the day-to-day workings of the drug discovery environment. Their challenge is to provide the intellectual framework to use this data to find drugs rather than play a technology-driven numbers game.

Acknowledgment

The present text is a modified and updated version of the chapter ''Receptor-Targets in Drug Discovery and Development'' published in ''Burger's Medicinal Chemistry and Drug Discovery'' (ISBN 0-471-37032-0) edited by D.J. Abraham in 2003.

Bibliography 700
Books and Reviews 700
Primary Literature 700

Keywords

Action potential
An all-or-none transient electrical depolarization propagated in excitable tissues.

ADH
Antidiuretic hormone or vasopressin; peptide hormone from the pituitary that controls plasma osmolarity by regulating aquaporins in the apical membrane of renal Principle cells.

Aldosterone
Adrenal steroid hormone that controls plasma volume and salt balance by regulating EnaC channels in the apical membrane of renal Principle cells.

Allele
The specific sequence of a given gene. Each possible variation of that sequence, functional or not, reflects a different allele.

Apical membrane
The specialized face of an epithelial cell that generally faces into the lumen of the gland and often is folded into a brush border with microvilli.

Aquaporin
A transmembrane protein that allows the transport of water free of solvated ions.

Ataxia
Inability to coordinate voluntary muscle activity, generally due to defect in cerebellum or spinal cord.

Channel
Transmembrane protein that allows the conductive transmembrane transport of small molecules, most commonly ions and water.

Channelopathy
A disease originating from dysfunction of a channel, or channel-like membrane protein.

Depolarization
A change in membrane potential tending to make the cell interior more positive.

Diuretic
A drug that serves to enhance urine flow, generally by acting to inhibit a renal sodium transport mechanism.

Dominant Allele
One copy of a mutation is sufficient to produce the mutant phenotype, such that the heterozygote expresses the phenotype.

Dominant Negative Mutation
A dominant mutation that results in less activity of the gene product than would be produced in a heterozygote with one wild-type and one null allele. Most commonly occurs because gene product functions as an inhibitory subunit in protein multimer.

EKG
Electrocardiogram; standardized clinical recording of extracellular electrical activity generated by the heart.

EMG
Electromyogram; standardized clinical recording of electrical activity generated by muscle contraction.

Environmental Disease
A disease caused by an agent external to the host.

Epilepsy
A chronic condition of seizure susceptibility, characterized by paroxysmal brain dysfunction and synchronized neuronal depolarizations.

Epithelium
A coupled sheet of polarized cells.

Excitation-contraction Coupling
The process by which electrical depolarization of a muscle membrane leads to activation of contractile fibers and cell contraction.

Gain-of-function Mutation
A mutation that increases the activity of the gene product to any degree.
Syn = hypermorphic.

Gate
Portions of channel protein that close access to permeability pore and is operated in response to ligand binding, voltage, or other stimulus.

Gene Family
An assembly of genes related by sequence homology, likely reflecting decent from a common ancestor followed by divergence.

G-protein Coupled Receptor
A large family of membrane proteins having seven transmembrane spans, the prototype being rhodopsin, which serve in sensory transduction by coupling to a signaling cascade through trimeric GTP binding proteins.

Haploinsufficiency
A mechanism of dominant inheritance whereby a heterozygote with one wild-type and one null mutant allele manifests the mutant phenotype. This is an atypical situation since rarely is 50% of wild-type activity insufficient for physiological function.

Heteromultimer
A combination of protein product subunits encoded by distinct genes uniting to produce a functional protein assembly.

Heterozygote
An individual having two different alleles of a gene. The default use implies that one copy is wild-type and the other mutant; however, this can also be an individual having two different mutant alleles, in which case they are specified.

Homozygote
An individual having identical copies for both alleles of a gene. These can both be wild-type or mutant.

Hypermorphic
A mutation that increases the activity of the gene product to any degree. Syn = gain of function.

Hyperpolarization
A change in membrane potential tending to make the cell interior more negative.

Hypomorphic Mutation
A mutation that inactivates the gene product to any degree. Syn = loss of function.

Inactivation
A nonconducting conformation of an ion channel from which it is incapable of carrying out an activating transition into a conducting conformation.

Ion channel
A transmembrane protein that allows the selective transport of ions freed from solvating water.

Ligand-gated Ion Channel
Binding a chemical compound to a site on the channel protein operates the gating mechanism to open or close substrate access to the permeability pore.

Loss-of-function Mutation
A mutation that inactivates the gene product to any degree. Syn = hypomorphic.

Loss of Heterozygosity
Regional loss of the chromosome carrying a normal copy of a gene, exposing clinical manifestations of a recessive mutation that is otherwise carried silently on the other copy of the chromosome.

Mendelian Disease
The same as a monogenic disease. Its inheritance follows Mendel's laws and can be either dominant or recessive.

Migraine
A condition characterized by paroxysmal onset of severe headache, generally unilateral, often associated with vertigo, nausea and photophobia and proceeded by a sensory aura.

Miniature Endplate Potentials (MEPPs)
Spontaneous depolarizations recorded at the motor endplate, which represent postsynaptic neuroreceptor response to spontaneous quantal release of neurotransmitter vesicles into the synapse.

Monogenic Disease
A disease caused by a major-effect gene mutation, such that the presence of this one mutation alone is highly predictive of the disease phenotype.

Motor Endplate
Postsynaptic membrane of specialized synapse of the motor neuron onto the skeletal muscle sarcolemma.

Myotonia
Delayed relaxation of skeletal muscle.

Neomorphic Mutation
A mutation that conveys to the gene product a new activity not present in wild-type.

Nernst Equilibrium Potential
The electrical potential difference at which no net ionic flux is observed across a permeable membrane despite the presence of a concentration difference between the sides. $E_K = [RT/nF] \ln[K_o/K_i]$ gives the Nernst potential for potassium, E_K, where R is the gas constant, T the absolute temperature Kelvin, n the valance, F the Faraday constant, and K_o and K_i the extracellular and intracellular potassium concentration, respectively.

Neuromuscular Junction
Specialized synapse of the motor neuron onto the skeletal muscle.

Null Mutation
A total loss of gene function, the extreme limit of a hypomorphic mutation, can include deletion or disruption (as in a knockout allele) of the gene itself.

Pacemaker
Endogenous source of rhythmic activity. In the heart, this is the sinoatrial node and the rhythm arises via spontaneous depolarization of the membrane.

Paracellular
Pathways across an epithelial sheet that pass between cells.

Paralysis
Inability to contract muscles.

Patch Electrode
Fire-polished glass electrode with 1-μm tip diameter that forms a molecularly-tight high resistance seal when applied to cell membrane, allowing recording from single channel molecules.

Pathophysiological Mechanism
Alteration in biological function leading to a disease process. This can be resolved from the molecular to the organismal and ecological levels.

Permeability Pore
Pathway though the channel protein taken by the conducted substrate.

Pharmacogenetic Disease
A disease caused by the interaction of an inciting ''triggering'' drug and an individual with a susceptible ''at risk'' genotype.

Plateau Phase
Segment of the cardiac myocyte action potential that coincides with the QT interval as observed on the EKG.

Polygenic Disease
A disease caused by an assembly of minor-effect gene mutations, such that the presence of any one of the mutations contributes only a small additional susceptibility to the disease.

Primary Active Transport
A transmembrane transport process that is capable of moving a substrate against its electrochemical potential gradient by directly utilizing the chemical energy of ATP hydrolysis.

QT Interval
The phase of cardiac ventricular repolarization as observed on the EKG. This coincides with the plateau phase of the cardiac myocytes action potential.

Recessive Allele
Carrying one copy of the mutation, the heterozygote appears like wild-type, not mutant. Only when both gene copies are mutant is the mutant phenotype observed.

Resorptive Epithelium
An epithelial sheet designed to create a flow of salt and water out of the lumen and into the blood.

Sarcoplasmic Reticulum
The specialized endoplasmic reticulum of skeletal muscle cells.

Secondary Active Transport
A transmembrane transport process that is capable of moving a substrate against its electrochemical potential gradient by coupling to the electrochemical potential of another chemical species, often sodium.

Secretory Epithelium
An epithelial sheet designed to create a flow of salt and water into the lumen and out of the blood.

Segregation
The disjunction of homologous chromosomes at meiosis such that offspring receive only one copy of each parental chromosome. This process underlies the characteristic Mendelian patterns of inheritance.

Seizure
Paroxysmal brain dysfunction associated with synchronized neuronal depolarizations.

Selective Advantage
An attribute of an allele that evolution favors, reflected by the survival of an excess of its descendants in subsequent generations.

Selectivity Filter
Portion of channel protein that restricts conductance to only specific substrates.

Splice Variant
Gene products that result from the use of alternative exons, often by exon skipping.

Subcellular Compartment
Membrane enclosed regions within eukaryotic cells. Examples include the endoplasmic reticulum, Golgi, mitochondria, and lysosomes.

Toxin
A natural biomolecule with potent biological activity. Ion channel toxins typically act to block or open ion channels at picomolar concentrations.

Transcellular
Pathways across an epithelial sheet that go through the cytosol.

T-tubules
Specialized invaginations of sarcolemma that play specialized role in excitation-contraction coupling of muscle fiber contraction.

Voltage Clamp
A feedback amplifier that adjusts externally applied current across a membrane such that the membrane potential is kept at a constant value even though its permeability character is varying.

Voltage-gated Ion Channel
Ion channel that is gated in response to changes in the membrane potential.

Wild-type
The allele of a gene most abundantly found in nature, for simplicity this can be considered the normal, nonmutant version of the gene.

Ion channels reflect an important but still very new mechanism of disease, first formalized in 1989 with the discovery of mutations in the *CFTR* ion channel gene causing cystic fibrosis, thereby carving out a new category of genetic inborn error, the channelopathy. Now, however, ion channel disorders are recognized to cover the gamut of medical disciplines and to cause significant pathology in virtually every organ system. The opening of this era was driven largely by the success of positional cloning strategies in isolating the genes underlying the rare monogenic disorders of ion channels and the explosive growth in basic ion channel physiology and biophysics that rendered these pathogenic mutant alleles interpretable, but in addition crystal structures have recently become available. Ion channels are a large family of over 400 related proteins representing over 1% of our genetic endowment, and many of the features shared among the rare monogenic ion channel diseases provide a solid foundation to begin to target these mechanisms for the development of novel therapeutics. They also render members of this gene family important ''functional candidates'' in the much more common complex polygenic diseases.

1 Introduction

Ion channel diseases reflect a relatively new category of genetic disease, or inborn error. Monogenic Mendelian ion channel diseases, or *channelopathies*, were first recognized in 1989 with the isolation of pathogenic alleles causing cystic fibrosis. The field explosively advanced as positional cloning revealed new pathogenic loci and alleles, and patch electrode

electrophysiology allowed detailed characterization of the functional effects of mutations. This work most powerfully converged in the dissection of components of the action potential of excitable tissues – nerve, muscle and heart and while it remains true that diseases of excitable tissue still most clearly illustrate this family of diseases, ion channel disorders now cover the gamut of medical disciplines, causing significant pathology in virtually every organ system, producing a surprising range of often unanticipated symptoms, and providing valuable targets for pharmacological intervention.

2 Physiological Function of Ion Channels

Ion channels are a large family of related transmembrane proteins that provide ions, predominantly K^+, Na^+, Ca^{++}, and Cl^-, a passive pathway through which they can rapidly diffuse down their electrochemical gradient across the hydrophobic barrier of the plasma membrane. The standing electrochemical gradients that drive ion movements though channels are established by ion pumps – such as the Na/K-ATPase, and ion carriers – such as the Na-K-Cl cotransporter and the Na-H antiporter. While classical kinetic studies portray channels, pumps, and carriers as radically different transport mechanisms, with channels conducting ions 4 orders of magnitude faster and seemingly quite differently than the one-at-a-time transmembrane turnover of the pumps and carriers, we now recognize much similarity in their molecular mechanisms. Most cells maintain a high intracellular K^+, and a low intracellular Na^+ and Ca^{++}, compared with the surroundings, while Cl^- is often passively distributed at its *Nernst equilibrium*, which in a cell with a typical −60 mV membrane potential (inside negative) would be 10-fold lower on the inside (i.e. $E_{Cl^-} = (RT/nF) \log [Cl^-]_i/[Cl^-]_o \sim -59$ mV). The K^+ gradient, created at the cost of ATP hydrolysis by the ion pumps, is typically 10-fold in mammalian cells, and since the K^+ permeability, P_{K^+}, of most membranes overwhelms that of other ionic species, the K^+ diffusion potential predominates, setting the cell membrane potential, and giving rise to the typical −60 mV resting membrane potential near E_{K^+}. *Note that the physiological ions both create and respond to electrical phenomena across the cell membrane.*

In many ways, channels act like highly selective water filled pores that can be opened and closed in a controlled fashion to allow a specific ion species to flow, a flow that in turn can be perceived as both a miniscule chemical flux, with the use of isotopic tracer, or, more commonly, as an electrical current that changes the membrane potential toward the Nernst potential of the conducted ion, an interior positive *depolarization* created by opening Na^+ and Ca^{++} channels, an increasingly negative *hyperpolarization* created by opening K^+ channels, and a stabilization of the membrane potential by opening Cl^- channels. Note that unlike enzymes, channels carry out no biochemical transformations; the product and substrate ions differ only in regard to the side of the membrane on which they are found. Ion channels are further distinguished from enzymes in that rarely is the transported ion itself of any physiological consequences, since the flux through channels minimally changes the ion's concentration across the cell membrane; it is predominantly the electrical consequences of the ion current flow that underlies the physiology of the ion channels. Calcium is often an important

exception to this rule, since it plays a critical role in coupling electrical activity to biochemical pathways. A second exception is that the chemical consequences of ion channel flux often predominates their function in epithelial cells.

We now recognize that ion channel proteins have structures that impose the three cardinal functions of a channel mentioned above: a *permeability pore* that provides ions but not water a passageway across the bilayer, a *selectivity filter* that allows some ions access while excluding others, and one or more *gates* that opens and closes the passageway. Three eras of Nobel Prize-winning technological and conceptual breakthroughs have led to our current level of understanding channel function (Fig. 1). All three key features of channel function were first defined, as abstract entities modeled with mathematical exactitude, in the era of the pioneers in membrane biophysics, an era that was opened up by *voltage clamp* technology fifty years ago and crowned by the Nobel Prize-winning classic squid axon studies of Hodgkin and Huxley (Fig. 1a). However, recent Nobel Prize-winning crystallographic work from the lab of Rod MacKinnon has now defined all three aspects in exquisite molecular detail for at least a few prototype channels (Fig. 1c). An essential era linking the mathematical and structural eras was that brought about by the breakthrough of *patch electrode* electrophysiology and crowned by the Nobel Prize-winning work of Neher and Sakmann. This era was critical in defining channels as biochemical mechanisms, and worked hand-in-glove with the molecular genetics of gene isolation and *in vitro* expression studies of cloned wild type and mutant channels, a breakthrough enabling paradigm pioneered in the lab of Shosaku Numa. Since the patch electrode would seal onto the plasma membrane so tightly that ions, and therefore ionic currents, could not leak between the two structures, magically tight gigaohm seals could be achieved that allowed electronic amplifiers the sensitivity to monitor in real time a single ion channel molecule in its millisecond stochastic dance between conformations: ''closed,'' where it is nonconducting, and ''open,'' where it passes on the order of 10^7 ions s^{-1}, producing a current of 10^{-12} amps, a picoamp, with stochastic transitions between the two states giving rise to the beautiful square wave traces of single-channel current records that are emblematic of the era (Fig. 1b).

One can separate the greater family of ion channels into various large classes based upon the cardinal channel features of selectivity and gating. One major distinction is based upon the nature of the selectivity filter and the predominant permeant ion species: hence, since the era of Hodgkin and Huxley, there have been K^+ channels, Na^+ channels and so on (Fig. 1a). Another major classification is based upon the gating mechanism. One large class of channels gate in response to their direct binding of ligand – the *ligand-gated ion channels*. Many of these ligands are classical neurotransmitters: hence, there are acetylcholine-gated ion channels, dopamine-gated ion channels and so on. But a wide range of other types of extracellular and intracellular ligands are also able to directly gate ion channels through binding. In addition, a large family of ion channels is indirectly gated by ligands, many by the same neurotransmitters mentioned above, but in this case neurotransmitter binding occurs to a heptahelical *G-protein coupled receptor* (GPCR) and the channel is activated by a second messenger ligand or a covalent modification, such as a protein

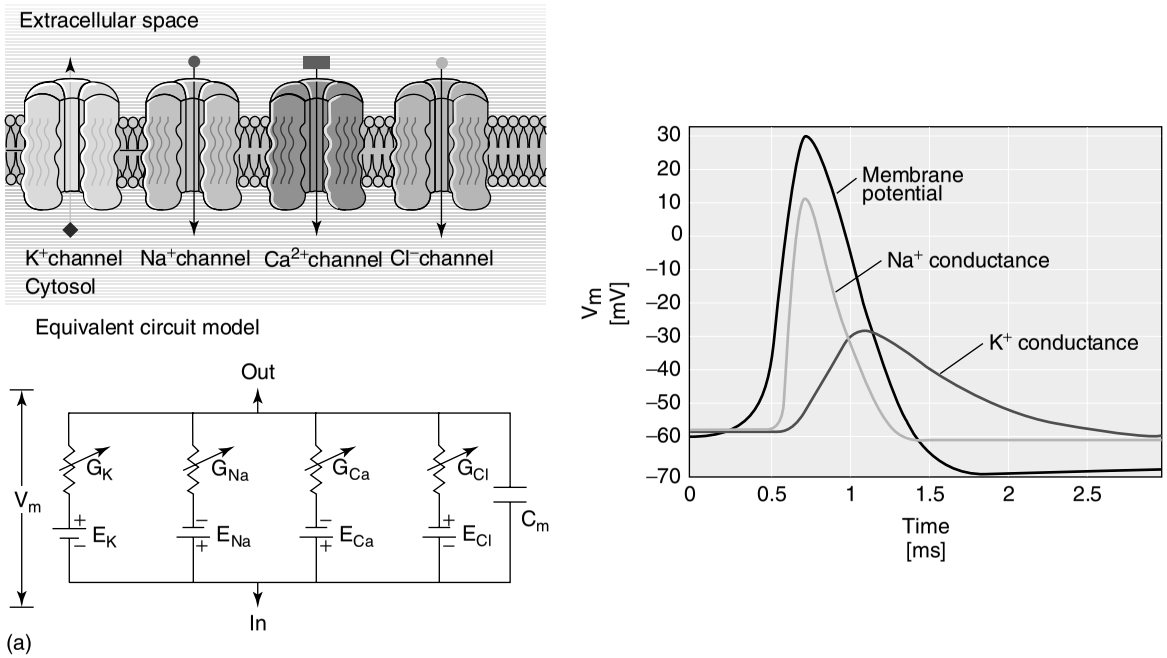

Fig. 1 3 ERAS of the ion channel. (a) Hodgkin–Huxley era, (b) Patch-clamp era, (c) Crystallography era.

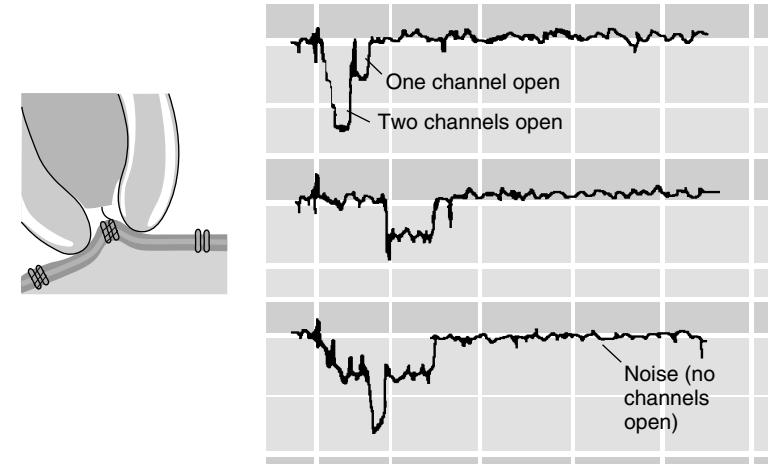
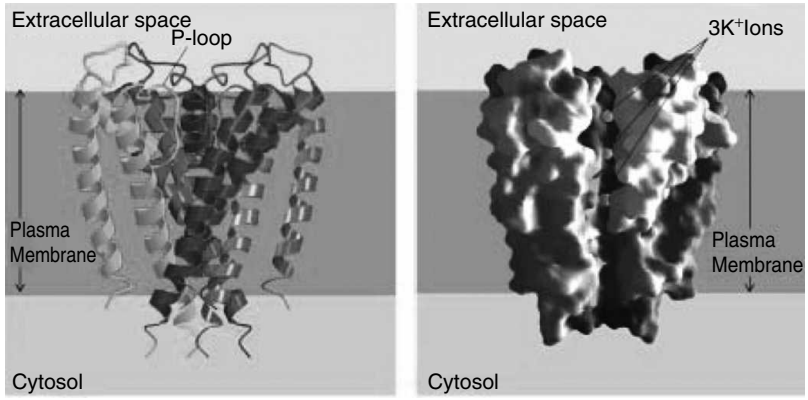


(b)



(c)

Fig. 1 (*Continued*)

phosphorylation or dephosphorylation reaction. Finally, a very large class of ion channels gate in response to changes in the electrical potential across the membrane, the *voltage-gated ion channels*. You can imagine that these are particularly tricky to study since the channel's own ionic current that is being controlled by the membrane potential *itself* alters the membrane potential, a vicious cycle that could only be broken by the voltage clamp amplifier. This experimentally vexing behavior of voltage-gated ion channels is, however, critical to their function in the perpetuation of a *propagating action potential* (AP). As a patch of membrane begins to depolarize, often because of the activation of a ligand-gated channel, voltage-gated Na^+ and Ca^{++} channels begin to respond to the voltage change by undergoing a conformational change from the ''closed'' into the ''open'' conformation (Fig. 2), increasing the membrane's permeability to sodium and calcium (P_{Na^+} and $P_{Ca^{++}}$) and hence

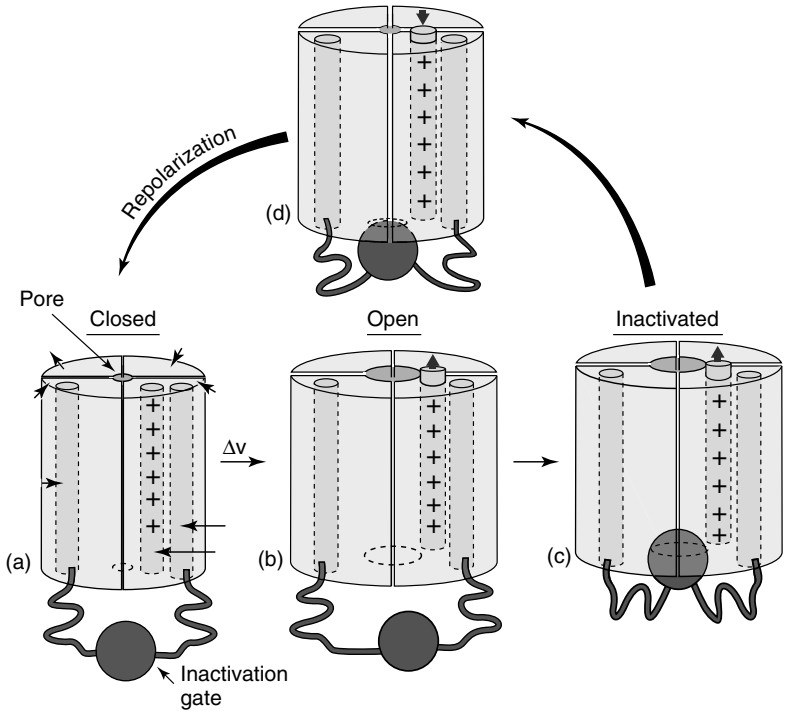


Fig. 2 Three states of the channel.

driving the membrane potential toward *their* inside-positive Nernst potential, a depolarization that serves to further activate more channels in surrounding patches of membrane in an explosive self-reinforcing cycle, recognized as a propagating AP, a depolarizing wave that rapidly spreads through an excitable tissue until all of its channels have been activated. Those channels next spontaneously enter an *inactive*, nonconducting conformation that is distinctly different from the ''closed'' state, since while ''inactive,'' a channel cannot be opened and the tissue is rendered nonexcitable. Only by restoring the resting membrane potential does the channel's conformation become reset to the ''closed'' state that has the potential to open, and excitability is restored to the tissue. This resetting and restoring job is carried out by the more slowly activating voltage-activated K^+ channels. Since cells have but one membrane potential, it is always integrating inputs from all channel mechanisms in the membrane, and for this reason it is the great integrator in signaling pathways. Also, unlike biochemical pathways whose overall flux is predominated by a single rate-limiting step, membrane potential is intrinsically a continuous variable fully reflecting subtle changes in the entire host of contributing channels.

3 Biochemical Structure of Ion Channels

Ion channel proteins share many structural features in common that today allow

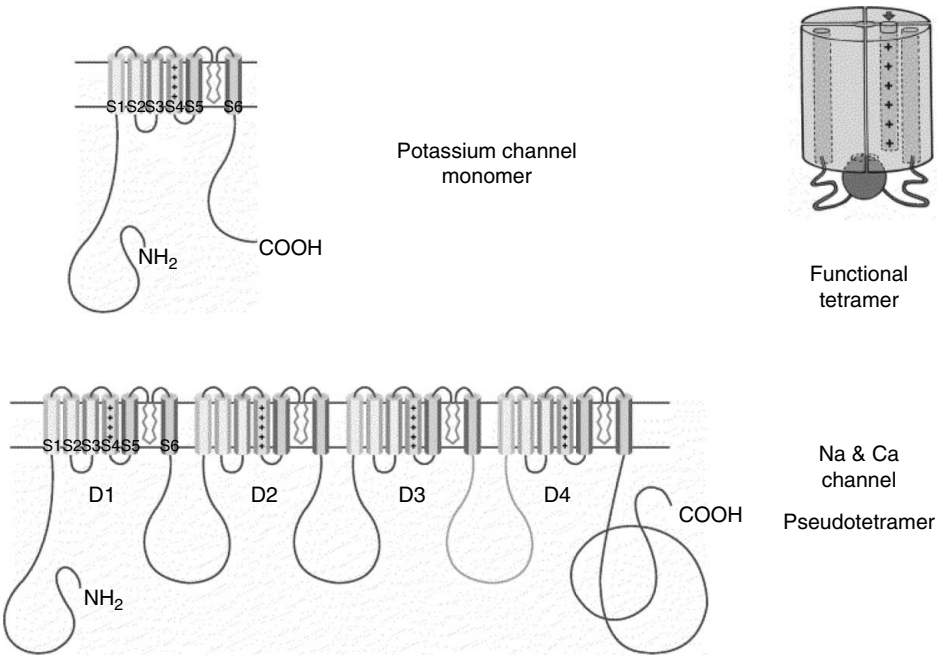

Fig. 3 Voltage-gated channels.

us to model their consensus structures and functions based upon the few prototype channel structures that have emerged from crystallography (Fig. 1c). For example, the large superfamily of voltage-gated potassium channels share a monomer structure of 6 transmembrane helices, each helix characteristically 20 to 25 amino acids in length, and both the N- and C-termini facing the cytosol (Fig. 3). The N-terminus forms a tethered ''ball and chain'' motif that gates the channel under the influence of electrostatics and the altered membrane potential its activation has brought about. It does this by swinging into the inner mouth of the pore and thereby effects the ''opened'' to ''inactive'' transition of the channel. The forth helix characteristically contains a cluster of 4 to 8 positively charged residues, converting that helix into a dipole that allows it to move under the influence of the membrane potential. This allows it to serve as the voltage sensor that gates the channel from the ''closed'' to the ''opened'' conformation. Between the fifth and sixth helix is found the heart of channel function, a signature pore domain characterized by a hairpin motif that dips partially through the membrane to form the conductive pathway used by the ion (Fig. 4). Some families of channels, such as the inward rectifiers, contain only this pore and the two flanking helices (Fig. 5). This pore domain contains the K^+ selectivity filter, a nonhelical motif conveyed by the amino acid sequence, TVGYG. It is, however, the strongly dipolar carbonyl groups of the α-carbons in the peptide backbone of this amino acid sequence, not the specialized side chains, that line the pore and create, through electrostatics and geometry, the selectivity filter that allows potassium ions

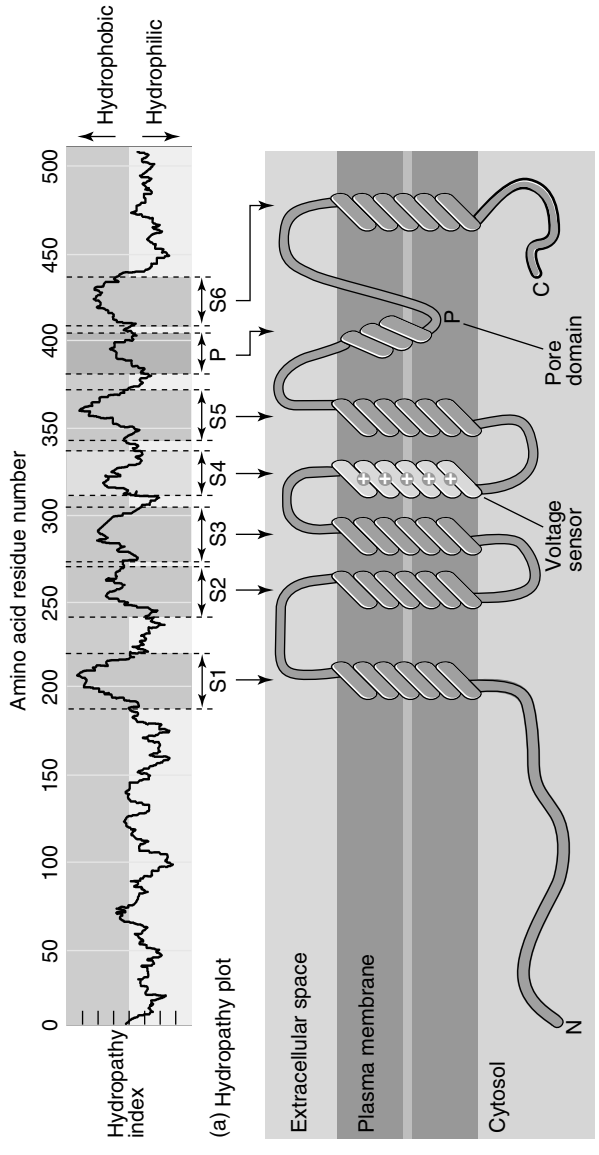

Fig. 4 Hydropathy plot and secondary structure prediction of amino acid sequence of potassium channel monomer.

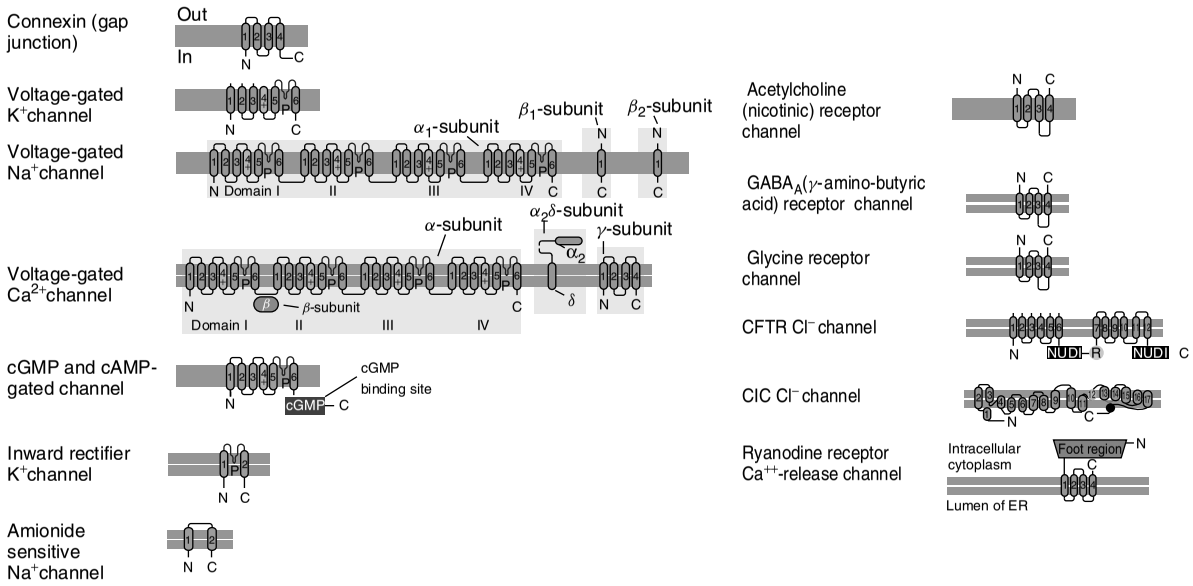

Fig. 5 Secondary structure of channel families.

entrance, but excludes sodium and other ions. The functional potassium channel that creates the transmembrane pore is a tetramer and the overall structure of the tetrameric assembly is that of an inverted teepee created by the tertiary structure of the fifth through sixth helices of the four interacting subunits, with the large vestibule of the teepee facing outward and lined by the selectivity filter residues from each monomer (Fig. 1c). Helices 1 to 4 of the monomers surround this core structure and present a surface that interacts with the lipid bilayer. Upon channel opening, the potassium ions move in a single file fashion along the pore, rapidly hopping between interactions with each of the critical residues of the filter motif, thousands of ions flowing during each channel's opening.

Conserved features that families of ion channels share in common have also proven useful in the identification of their genes in the genome. The human genome contains over 400 channel genes representing between 1 to 2% of our genetic endowment, although the substrate transported by most remains to be identified. While there are already known several large families of ion channels that apparently carry out extremely similar biochemical functions (Figs. 5 and 6), for instance, over 100 voltage-gated channels, the large number of channel genes almost certainly does *not* reflect redundancy. Since their job is not primarily contingent on their ability to transport ions from one side of the membrane to the other, but rather on the shape of the electrical signal they produce during conductive ion flow, it is apparently this that is under evolutionary selective pressure and it suggests that physiology requires the diverse vocabulary provided by multiple members of a gene family, which carry out nearly indistinguishable transport reactions with subtly differing kinetics. Furthermore, it is becoming increasingly clear that gene-family diversity is additionally greatly expanded through alternative exon splicing, allowing one channel gene locus to produce multiple splice isoforms and hence multiple functionally distinct protein products. Finally, for at least a handful of channels, and best characterized in the glutamate receptor channels, the exotic complex process of RNA editing is carried out to change single amino acid residues in the permeability pathway that critically tune ion selectivity and other aspects of channel function. Clearly, very subtle differences in channel function are important since evolution seems to have gone to very great lengths to preserve and enhance channel gene diversity.

For the potassium channels, diversity is further tremendously amplified through combinatorial monomer assembly into the functional tetramer (Fig. 3). This predominantly arises because channel protein subunits encoded by all members of a channel gene *family*, not just the allelic splice-variant protein products, coassemble to create a functional channel that differs in biophysical behavior as a function of the stoichiometry of the constituent subunits in the assembly. The panoply of combinatorial heteromultimers formed as monomers from family members coassemble, creates tremendous functional diversity in the potassium currents. This finely tunes the behavior of the population of expressed functional channels. This diversity conveys the essence of potassium channel function, allowing them to be tuned to modulate signal processing as they interact and jointly shape the membrane potential, thereby ''deciding'' the cell's aggregate signaling output.

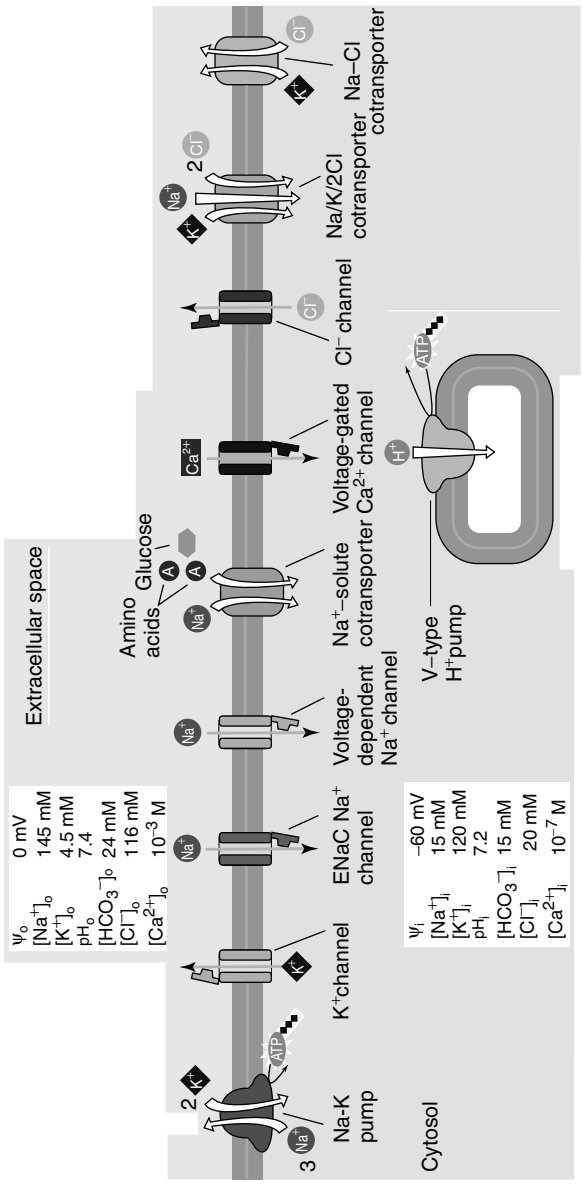

Fig. 6 Ion pumps, carriers, and channels.

In contrast to the broad heterogeneity of composition and function of the ''contemplative'' potassium channels, the voltage-gated sodium and calcium channels that are the ''do-ers,'' able to execute the result of signal processing, are extremely homogeneous in their structure and function in a given tissue. While they can be perceived to share the structure of the potassium channel monomer, in their case, where a crisp uniformity of channel function is required within a tissue, a fixed pseudo-tetramer structure is hardwired into the large endoduplicated genes that encode a pseudotetrameric functional monomer (Figs. 3 and 5). Tissue-specific diversity in the function of these channels is conveyed by tissue-specific isoforms of the gene family of voltage-gated sodium and calcium channels.

In addition to the major, α, channel subunits that directly contribute to the conducting pore of ion channels, discussed above, there are also a host of auxiliary subunits, each represented by gene families often labeled $\beta, \gamma, \delta, \varepsilon$, that modify channel function (Fig. 5). This obviously adds another enormous combinatorial explosion of channel diversity. Much of this diversity allows channel function to be tuned for its specific use in a specific tissue, since many channel genes are expressed in a remarkably tissue-selective fashion. On the other hand other channels may be found to be broadly expressed, but to predominate in the physiology of only a few tissues. As will become clear below, both of these features allow channels to produce tissue-selective disease. This tissue selectivity also points out that ion channels should offer highly focused targets for therapeutic intervention, perhaps devoid of the cross-tissue ''side effects'' that complicate many current receptor-based drug targets.

4 Ion Channels as a Mechanism of Disease

4.1 Contribution of Genes and Environment to Disease

While classically diseases are recognized to arise from a host of extrinsic environmental causes, such as infectious agents, or from intrinsic causes, most simply a reflection of our genes, we now recognize that genes and the environment are inextricably connected in all disease, and in most we see various contributions from a small number of ''major-effect'' genes, smaller contributions from a large number of ''minor-effect'' genes, and variable contributions from a host of factors in the environment. While recognizing this interconnectedness of genes and environment, we still tend to refer to diseases as being ''caused'' by the most salient of these three factors, the *monogenic* diseases, the *polygenic* diseases, and the environmental diseases. *Most parsimoniously, disease reflects a mismatch between genotype and environment.*

4.2 Monogenic Ion Channel Disease

Rare mutations arise *de novo* in the population each generation, breaking the molecular mechanism encoded by every gene in the genome in every possible way, most mutations being either neutral or deleterious to the gene's function; should the effect disrupt a critical physiological pathway, they are ''disease-causing.'' *Dominant* mutations are expressed in a phenotype even in the presence of one normal allele, so the phenotype occurs in the individual in whom they first arise; those producing a phenotype incompatible with reproduction being immediately

eliminated from the population, but being constantly replenished though new mutations. Thus, dominant mutations that are maintained and transmitted in the population tend to produce a later onset or milder course of disease. Recessive mutations that arise *de novo* are carried silently in a *heterozygote*, only rarely producing a disease on those rare occasions when two copies of the mutant gene are contributed to a *homozygous* offspring of two rare heterozygotes, this likelihood tremendously enhanced in a consanguineous mating. As most recessive alleles in the population are carried in heterozygotes, even lethal homozygote phenotypes have little effect on the disease-allele's frequency. On the other hand some ''disease-causing'' alleles are now very abundant in a given population, exceeding 1% of the population's alleles, frequencies typical of *polymorphic variants* that are commonly considered to be of ''neutral'' functional significance. An example of such a common polymorphism, carried by approximately 1 in 20 Caucasians, is the mutation that causes the most common genetic disease in Caucasians and the first recognized genetic ion channel disease, cystic fibrosis (CF). To understand the apparent anomaly of a lethal mutation rising to such abundance, a historical perspective is required. Often such high ''deleterious'' allele frequencies arise because of some *selective advantage* conveyed to the heterozygote carrier. In other instances, it simply appears that by chance heterozygotes for a rare mutation were among the founders who established an isolated population; with inbreeding, this allele became abundant and the disease frequency in this isolate became appreciable. Many common disease-causing mutations seem to have served in our evolutionary past as primitive ''inoculations'' protecting heterozygous carriers, who possess most of the ''disease-alleles'' in the population, against specific disease agents. The best-known example is the assent of the globin sickle cell and thalassemia hemolytic anemia alleles in the malaria belt, but CF alleles appear to be particularly protective against the infectious secretory diarrheas that imposed a high infant mortality in our recent past. While carrying two copies of the common CF allele is sufficient to produce a disease phenotype, independent of the contribution of other genes or environmental agents, and hence is recognized as a monogenic disease, the rare, nonpolymorphic mutant alleles of genes more commonly cause the rare monogenic diseases, such as the Long QT syndrome ion channel disorder, or channelopathy, to be discussed below.

Diseases such as those discussed above, in which there is a major single gene contribution to the disease phenotype are classically recognized as monogenic or *Mendelian* genetic diseases. The classical Mendelian pattern of recessive disease arises most commonly from *loss of function*, *null*, or *hypomorphic*, mutations, predominantly in a situation where sufficient gene product is available from the sole remaining copy of an essential gene for homeostasis. The dominant pattern of inheritance commonly requires a *gain of function*, such that a phenotype is created even in the presence of a normal copy of the gene; this can be an enhanced normal *hypermorphic* activity, a *neomorphic* activity not present in the native protein, or an inhibitory activity, *negative-dominance*, generally arising from an inactivating multimerization with the native protein. An alternative mechanism of dominance is *haploinsufficiency*, the less common situation where 50% of the physiological level of the gene product is *not* enough for homeostasis and in such cases

a loss-of-function allele can be dominant. Even for these ''monogenic'' diseases we recognize that other genes in the genome and the environment still contribute to the disease phenotype, and these effects are acknowledged under the classical terms of *penetrance* and *expressivity*; two individuals carrying exactly the same two alleles of a major-effect gene may have vastly different phenotypes with one showing the classical disease and the other ranging from having such minor manifestations that no aspect of the phenotype reveals the presence of the ''disease genotype,'' in which case he is called *nonpenetrant*, to perhaps manifesting only a minor, yet still diagnostic, feature of the disease, in which case he would demonstrate the variable expressivity of the disease.

4.3 Polygenic Ion Channel Disease

The situation described above is magnified in the polygenic diseases, common diseases of ill-defined pathogenesis, such as hypertension, diabetes, and epilepsy, where typically one mutant gene is insufficient to create the disease phenotype, most of the genes still remain to be defined, and the pattern of inheritance observed is simply familial clustering, not the clear segregation patterns of recessive or dominant inheritance seen in the Mendelian disorders. While many gene loci contribute together to produce the common polygenic diseases, both common polymorphisms and rare mutant alleles seem to participate, and while major-effect genes play a very minor role in the population, not uncommonly rare Mendelian forms of the disease phenotype do occur, their etiological gene providing a peak into the pathogenic mechanisms likely underlying the common form of the disease, such as the monogenic channelopathies recognized to cause epilepsy in benign familial neonatal convulsions (BFNC), hypertension in Liddle syndrome, and diabetes in permanent neonatal diabetes (all to be discussed in detail below). Most polygenic diseases additionally have a significant environmental component, hence their more comprehensive title of *complex polygenic diseases*. The environmental component of these diseases can be recognized since even identical monozygotic twins, sharing all of their genes in common, are discordant for the disease phenotype a high percentage of the time.

4.4 Pharmacogenetic Ion Channel Disease

Finally, some diseases appear to be caused by environmental agents. However, we now recognize that only in the face of an appropriate ''at risk'' genotype is an appropriate physiological target available such that the agent can be a toxin. Should the toxin be fairly rare in the environment, such as a general anesthetic, it may appear initially to cause an idiosyncratic environmental disease, such as the lethal rare adverse reaction to anesthetics referred to as *malignant hyperthermia* (MHS). Much later it was recognized that specific heritable ion channel mutations cause one to be vulnerable to this syndrome, an individual inheriting an MHS allele being perfectly healthy, just at risk for malignant hyperthermia, and not developing the lethal disease phenotype until exposed to the inducing anesthetic. The recognition of major genetic and environmental components in the disease classifies it as a *pharmacogenetic* disease, and likely many of the idiosyncratic drug reactions we observe, either toxic or therapeutic, reflect this same phenomenon. On the other

hand, should the environmental agent be ubiquitous, such as phenylalanine, an amino acid found in all foods, a disease caused by an environmental agent may appear to be a genetic disease, in this case phenylketonuria (PKU), the archetypical ''genetic'' disease for which every newborn is screened, but which produces no disease phenotype if phenylalanine exposure is controlled.

4.5 Ion Channel Toxins

That ion channels are exquisitely sensitive, finely tuned, evolutionarily highly conserved mechanisms essential to an organism's physiology has not been lost to the combatants on Evolution's fierce battleground. Nearly all of the most potent toxins in Nature target ion channels, most with nanomolar to picomolar affinity. Tetrodotoxin from the puffer fish, saxitoxin from red tide dinoflagellates, and a huge number of scorpion and coelenterate peptide toxins target the voltage-gated sodium channels; ω-conotoxin from the cone snails and a host of spider venom toxins target the voltage-gated calcium channels; a number of scorpion, insect, and coelenterate toxins target families of potassium channels; α-bungarotoxin, from snake venom, and the Amazon blow-dart alkaloid toxin curare target the nicotinic acetylcholine receptor and the plant alkaloid picrotoxin targets the GABA receptor channel. Most toxins act by relying upon intimate, high-affinity contacts within the channel molecule, and for this reason many have proven to be essential tools in defining classes of ion channels and their mechanisms of action. Since most of these toxins are quite rare in the environment and none seem to have participated in major human evolutionary bottlenecks, nearly all human genotypes are vulnerable to these toxins, despite the fact that in the laboratory mutations can be selected to convey toxin resistance. For this reason, a huge array of toxins can be recognized to produce quite pure forms of environmental or toxic channelopathies.

4.6 Mechanism of Ion Channel Disease Pathogenesis

Ion channel diseases span the gamut of pathogenic mechanisms discussed above. Furthermore, the pathophysiological mechanisms that lead from a defective ion channel protein to a disease phenotype are complex and multifaceted. That Nature requires a genetic investment in the huge array of subtly differing channels leads one to expect that subtle changes in ion channels matter, foreshadowing the wide range of phenotypic abnormalities different mutants of the same gene might produce. It is therefore not surprising that ion channel diseases as apparently distinct as migraine and ataxia, paralysis, and myotonia or even as having dominant versus recessive inheritance, are found to be allelic, caused by different mutations in the same gene.

A *periodic* disturbance of rhythmic function is the cardinal feature of ion channel disease of excitable tissues. In the heart, this produces a fatal *arrhythmia*, observed as a loss of the normal synchronous contraction of the muscle composing the pumping chambers secondary to a disruption in the rhythmic action potentials arising in this electrically coupled tissue. In skeletal muscle, abnormal ion channel function produces periodic alterations in contractility, ranging from the inability to contract – *paralysis*, to the inability to relax – *myotonia*. And in the central nervous system (CNS), the rhythmic disturbance

is observed as an abnormally synchronous electrical discharge, a seizure. The remarkable finding in all of these syndromes is the absence of an overt functional abnormality the vast majority of the time. In the extreme, this results in the tragic situation where no phenotype is obvious until the moment of premature death. While many insights have been garnered as to how a variety of stresses serve to create the decompensations that allow these periodic phenotypes to become manifest, the mechanisms that serve to compensate for a constitutionally defective channel such that healthful homeostatic function is maintained the majority of the time, remain to be defined.

Ion channel phenotypes in nonexcitable tissues are more diverse because of the very different roles channels play in such tissues, participating in signaling involved in endocrine secretion, the function of cytosolic compartments and complex epithelial secretory and resorptive function, which in the kidney, produce secondary changes in systemic electrolyte balance and blood pressure.

It is simplest to develop the pathophysiology of ion channel disease by starting with the cardiac phenotype of arrhythmia and the Long QT (LQT) syndromes, demonstrating how the ion channels in the membrane work together in tissue function and how component parts of the membrane potential are dissected by the genetic lesions. It further provides specific paradigms for how subunit interactions can be manifest, how loss-of-function and gain-of-function phenotypes occur and how dominance can arise through either haploinsufficiency, gain-of-function, or in a ''dominant negative'' fashion. The muscle and CNS phenotypes, while not lending themselves to as simple a dissection of function are, however, easily built by extrapolation from this paradigm. They further illustrate the power of gene families in identifying candidate disease genes and reinforce the intrinsic polygenic nature of ion channel phenotypes. Finally, the nonexcitable tissue phenotypes can be used to show the range of functions ion channels carry out.

5
Ion Channel Diseases of the Heart

5.1
Function of Ion Channels in the Heart

Cardiac cells possess an intrinsic instability of their membrane potential, such that spontaneous depolarizing action potentials arise (as described at the end of Sect. 2 above), that can be observed as contractions in dissociated cardiac cells in culture. Muscle contraction is directly coupled to the propagation of an action potential, a phenomenon referred to as *excitation-contraction* (EC) *coupling*, since the calcium ions that enter the cell, amplified by other calcium sources inside the cell, produce the biochemical activation of the contractile proteins. Briefly, this entails calcium binding to troponin and releasing tropomyosin's block on myosin's cycling cross-bridge formation with actin. The electrical *pacemaker* function in a healthy heart only has the opportunity to manifest itself at the sinoatrial (SA) node, the physiological pacemaker of the heart. Since all of the other cardiac cells have a slower endogenous rate of spontaneous depolarization (pacing), and since all cells in the heart are electrically coupled, the fastest spontaneously depolarizing pacemaker, the SA node, is the origin of a propagated action potential that drives though the remaining cells of the organ,

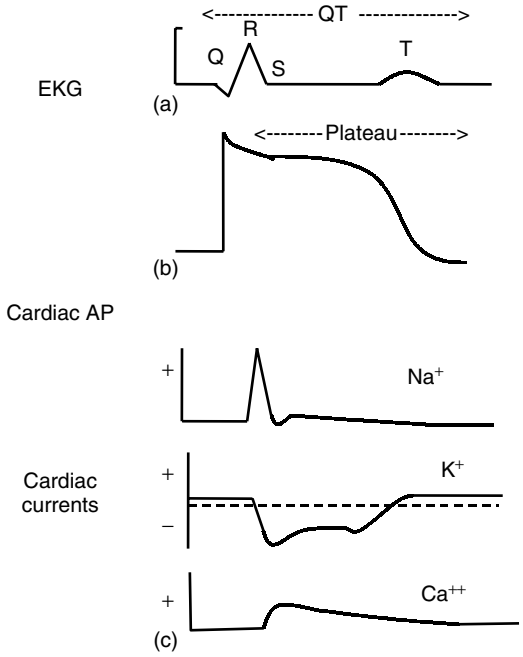

Fig. 7 Synchronized EKG, cardiac action potential and component currents. (a) EKG trace, (b) cardiac ventricle myocyte action potential, (c) resolved ionic currents underlying ventricular myocyte action potential. From Gargus, J.J. (2003) Unraveling monogenic channelopathies and their implications for complex polygenic disease.

forcing them to depolarize before they would do so spontaneously. Should the fastest pacemaker cells be lost, the next fastest pacemakers progressively take over, a very reassuring redundancy in a complicated process that must be repeated several billion times, failure rapidly resulting in death. The directional flow of the propagated action potential through the heart muscle creates the vector of the surface current revealed by the EKG traces, and produces a synchronous rhythmic coordinated contraction of the muscle cells composing the pumping chambers of the heart. If the cardiac cells of a pumping chamber all contract synchronously, the chamber volume rapidly shrinks, forcefully pumping blood that is directed by the cardiac valves. Without synchrony there is no pumping, only ineffectual fibrillation of individual cardiocytes and death to the individual. The cardiac pump cycle thus can be followed with the EKG. The QT interval measured on the EKG is the long interval of the cardiac cycle during which the ventricles, the major pumping chambers, repolarize, their conducted depolarizing action potential being reflected by the QRS waves (Fig. 7).

5.2 Ion Channel Dysfunction in Arrhythmia

A design feature engineered into the ventricular action potential by the mix of ion channels in its membrane is a prolonged plateau phase of depolarization, a phase *not* present in the classic rapid action potential of nerve (Fig. 1a). LQT syndrome is caused by mutations in the cardiac ion channel genes contributing to this component of the cardiac action potential. The plateau phase is a time during which calcium enters ventricular myocytes to produce contraction, but as importantly, the depolarized plateau phase serves to hold

sodium channels in the ''inactive'' nonexcitable state until the inciting depolarizing wave has spread to all of the electrically coupled myocardium. In this manner, it can be assured that all ventricular myocytes will repolarize and regain the ability to again depolarize in synchrony. If this mechanism fails, and one group of cells fires an action potential that cannot be conducted through a still-recovering inactive area, those inactive cells may subsequently have sufficient time to develop their endogenous pacemaker-like depolarization and asynchrony in the tissue is initiated as an endlessly looping futile depolarization wave spreads through any newly excitable domains of the tissue. Such asynchrony is lethal since unless the entire ventricular muscle depolarizes and contracts together, it does not pump blood, but only fibrillates. During the plateau phase, the membrane potential struggles between the depolarizing influence of sodium and calcium currents and the repolarizing influence of potassium currents, with the slowly developing potassium currents finally overcoming the depolarizing currents and restoring the resting membrane potential (Fig. 7). Mutations that serve to either enhance the sodium current or to reduce the potassium currents predictably prolong the plateau phase and are associated with LQT syndrome. A long plateau phase is a dangerous situation since prolonging it opens the opportunity for asynchrony between the cells and susceptibility to arrhythmia, as described above.

5.3 Long QT Syndrome

Classically the LQT syndromes are divided into those with a dominant pattern of inheritance and a phenotype limited to the heart, the Romano–Ward syndrome (RW), and those having recessive inheritance and a phenotype that includes sensorineural hearing loss, the Jervell and Lange-Nielsen syndrome (JLN). In addition, there are now recognized acquired forms of the disease, primarily developing in a failing heart, and pharmacogenetic forms, a serious complicating side effect for a wide spectrum of drugs. As the name suggests, LQT prolongs the QT interval measured on the EKG and predisposes to a fatal arrhythmia; however, typically the pedigree may only reveal early sudden death of no known etiology. There are no diagnostic pathological findings and commonly no symptoms before death such that the disease is commonly not diagnosed until repeated deaths in a family have occurred. Diagnosis of the syndrome, on the other hand, does not depend upon a clinically recognized phenotype; rather, it depends only upon the EKG findings. There is a characteristic context of death observed in the syndrome that further illuminates the critical balancing act performed by multiple cardiac channels in normal physiology. The context is that of excess adrenergic outflow, as occurs in high emotion or exertion. This is a risk since the heart rate dramatically increases during the ''fight or flight'' responses these transmitters mediate. While we may initially focus on this response in terms of the β-adrenergic receptor increasing the rate at which the cardiac pacemaker depolarizes and the heart contracts, it is clear that to depolarize more rapidly, it must also *repolarize* more rapidly, and in fact specific cAMP-dependent channel regulatory mechanisms downstream of the β-adrenergic receptor assure this coordination, effectively shortening the QT as the heart rate rises. This explains why the rational way to evaluate a QT is in the context of the underlying heart rate, the QTc. In a patient with an intrinsic LQT defect

that lengthens the QT, this adjustment of the rate of repolarization can not keep pace, the QT can not sufficiently shorten at high heart rates, and an arrhythmia ensues.

5.4 Nature of LQT Genetic Loci and Alleles

LQT mutations have been found in six cardiac ion channel genes. One LQT gene encodes the cardiac sodium channel and five encode the primary and auxiliary subunits of three different potassium channels (Fig. 8). While this provides a nearly complete dissection of the major channels involved during the critical plateau phase, one major actor, the cardiac calcium channel, encoded by *CACNA1C*, has yet to yield a pathogenic allele, perhaps being an early embryonic lethal. However, the most recently discovered LQT locus, LQT4, encoding ankyrin-B, while being unique in *not* encoding an ion channel protein, regulates a complex of transporters in the cardiac membrane mediating calcium homeostasis. *LQT1*, the first LQT gene identified, was found using a strategy involving linkage and positional cloning. All of the other LQT genes were identified as functional candidates within a mapped chromosomal interval.

5.5 The Dominant LQT Alleles

LQT1 was located on chromosome 11p 15.5, and it was ultimately demonstrated that mutations in a potassium channel α-subunit gene, *KCNQ1*, were causal. When expressed *in vitro*, *KCNQ1* produces a current that is not found in the heart; however, when expressed together with its β-subunit, encoded by *KCNE1*, they can be recognized to produce the I_{Ks} channel underlying the slow delayed rectifier K^+ current that participates in repolarization (Fig. 8). Over 35 different pathogenic alleles have been reported in this gene and they are the most common cause of RW syndrome. They primarily confer a dominant-negative phenotype when studied *in vitro*. Defective subunits coassemble with wild type copies producing, through combinatorials, a supermajority of defective channel tetramers, and hence reduced repolarizing current.

LQT2 was the first LQT gene cloned, taking advantage of a candidate gene approach within the region of chromosome 7q35–36 where a second locus was identified in families not mapping to chromosome 11. The gene, *KCNH2*, was a strong functional candidate based upon its homology to a fly gene with a proven ability to create a rhythm disorder phenotype, ether-a-go-go. Like *KCNQ1*, coexpression of *KCNH2* with its β-subunit, *KCNE2*, was required to produce a current that can be recognized in the heart. The channel they form is I_{Kr}, the rapidly activating delayed rectifier K^+ current (Fig. 8). Over 16 alleles of *KCNH2* have been reported, and like *KCNQ1*, many confer a ''dominant-negative'' phenotype when expressed *in vitro*. However, other dominant alleles appear to be simple loss-of-function alleles, suggesting that the membrane current conducted by this channel is so finely tuned that a haploinsufficiency mechanism is adequate to produce dominance.

LQT3 is the only sodium channel locus involved in the disease, and it is caused by mutations in the *SCN5A* gene found at chromosome 3p21–24. It encodes the cardiac-specific voltage-gated sodium channel that underlies the rapid depolarization phase of the ventricular action potential that produces the QRS complex and ventricular contraction (Fig. 8). Over 30 alleles of this gene have been

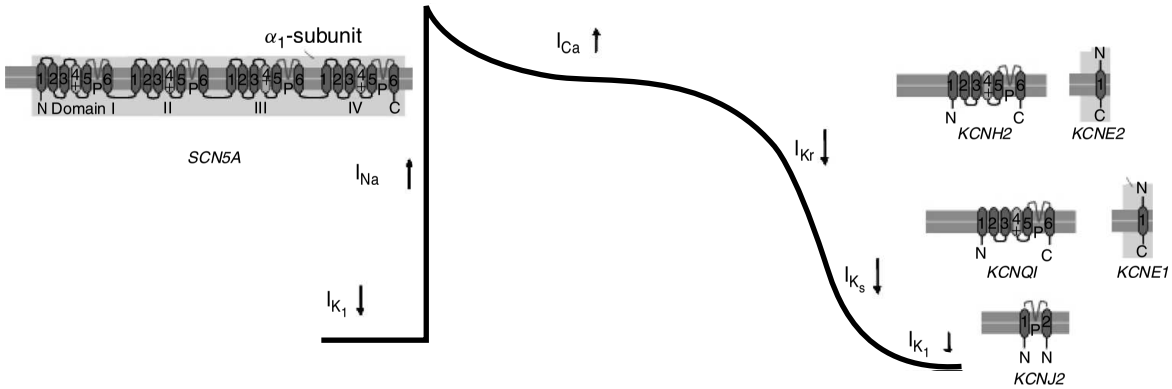

Fig. 8 Cardiac ion channel LQT genes. Each channel subunit gene product shown carries known LQT mutations. ↑ signifies depolarizing current, excess leading to LQT; ↓ signifies hyperpolarizing current, deficiency leading to LQT.

reported. Channels encoded by pathogenic alleles have delayed or decreased inactivation after opening, leaving excess inward depolarizing current during the plateau phase, delaying the time at which potassium currents can bring about repolarization. They are thus dominant ''gain-of-function'' mutations.

A distinct set of *SCN5A* alleles produce the *opposite* effect on inactivation from the *LQT3* alleles; they produce a rapid recovery from inactivation. They produce a different dominant arrhythmia syndrome, Brugada syndrome. The myocardium of these individuals contains a mixed population of sodium channels that are no longer locked in synchrony by a common period of inactivation, forming an ideal substrate for arrhythmia. Some alleles, surprisingly, are capable of producing either sodium channel phenotype within a family, demonstrating the delicate balancing act between excitation and inactivation carried out by the sodium channel that will be more clearly illustrated in the skeletal muscle disorders, and hinting at modifier genes that alter this balance, and therefore polygenic disorders.

LQT4 is the exception that proves the rule that LQT is an ion channel disease. The *LQT4* locus, found at 4q25 encodes ankyrin-b, a scaffold protein that colocalizes and regulates the Na/K-ATPase, the Na/Ca exchanger and the IP3 receptor. It is not a channel, but pathogenic loss-of-function alleles disturb calcium homeostasis through the functional loss of these critical mechanisms. It thus creates a dominant arrhythmia syndrome that includes LQT, but is not restricted to LQT.

LQT5 and *LQT6* are two adjacent loci on chromosome 21q22.1, and their genes, *KCNE1* and *KCNE2*, respectively, encode the two highly homologous potassium channel β-subunits discussed above as the accessory subunits that interact with their α-subunit partner to form I_{Ks} and I_{Kr}, respectively (Fig. 8). Both are proteins with only a single transmembrane α-helix and both function only to modify the behavior of the α-subunit with which they multimerize. Dominant pathogenic alleles are missense and effectively achieve dominance by altering channel gating to produce less current.

LQT7 is an alternative name for Andersen syndrome, a dominant multisystem disorder that includes long QT, but also extracardiac findings such as periodic paralysis and, more surprisingly, dysmorphology. Over nine different dominant-negative alleles of the potassium channel gene *KCNJ2* are responsible for this syndrome. The *KCNJ2* channel subunits multimerize to form the inwardly rectifying potassium channel that governs the resting membrane potential of the cardiac myocyte (Fig. 8). Current through this channel participates at the very end of repolarization, and hence dominant-negative loss of its function prolongs the process. The extracardiac findings imply that it also contributes in a significant way to membrane signaling in muscle and perhaps to the developmental processes underlying the dysmorphology.

5.6 The Recessive LQT Alleles

The recessive JLN syndrome differs from the dominant RW syndrome not only in its pattern of inheritance but also in its extracardiac manifestation of a constitutive sensorineural hearing loss. While in both syndromes the cardiac arrhythmia phenotype is lethal and intermittent, the striking differences between the two syndromes would never lead you to guess they might be allelic. In fact, the JLN alleles

are strong loss-of-function or null alleles in the same genes that cause dominant *LQT1* and *LQT5, KCNQ1* and *KCNE1,* the two channel genes encoding the I_{Ks} channel (Fig. 8). Surprisingly the same channel is expressed selectively in the heart and the inner ear, where its abundant expression is involved in the production of the potassium-rich endolymph fluid that fills this chamber and participates in the transduction of auditory sensation. Only complete loss of the channel significantly disturbs this secretory process. It is of note that another inner ear *LQT1* homolog, encoded by *KCNQ4,* has dominant alleles that produce only deafness without LQT (*DFNA2*).

5.7 Acquired LQT Channelopathies

While heart failure is the very common end-stage phenotype of a dilated and poorly contractile myocardial pump, and is produced by a variety of common insults to the heart, most deaths in this disorder arise from a fatal arrhythmia, and it likely reflects one of the most common forms of the LQT syndrome. The failing myocytes downregulate expression of potassium currents, perhaps in an attempt to enhance contractility by prolonging the period of calcium entry, the QT interval, but doing so predisposes them to the arrhythmia discussed above.

5.8 Pharmacogenetic and Polygenic Arrhythmia Syndromes

Initial studies suggested that LQT was a highly penetrant Mendelian phenotype with ''strong'' alleles that, while clinically silent, would dependably be revealed by EKG. Not surprisingly, it has become clear that there are both ''weak'' and ''subclinical'' alleles of these genes as well and likely polygenic interactions between them. Additionally, there is clearly an environmental component to the disease, seen as a pharmacogenetic syndrome, which greatly broadens the scope of the diseases involving these cardiac ion channel genes. These more subtle features of the disease became most apparent in studies on families initially considered to have a case of ''sporadic'' LQT. While half of the ''sporadic'' probands in the study had the predicted new dominant mutation in one of the LQT genes, the other half were found *not* to have new mutations, but rather to have families segregating a ''weak'' pathogenic LQT allele. This allele in these families had many silent carriers with no EKG abnormality, or they had carriers who only expressed the abnormality once taking a medication with potassium channel blocking activity. The silent carriers presumably lacked a phenotype because they lacked other unidentified susceptibility alleles at other loci carried by the proband. It is easy to imagine, based upon the descriptions above of the interactions between the multiple normally and abnormally functioning cardiac ion channels in maintaining and terminating the plateau phase of the cardiac action potential, how minor functional variants in these same genes could sum with one another to produce a major alteration in the plateau phase and hence produce a polygenic LQT, arrhythmia or sudden death phenotype. It is likewise easy to imagine how they might sum with a drug effect that acts like one of these mutations by blocking a potassium channel.

The pharmacological induction of the phenotype in an individual such as those in the Priori study suggests that environmental or genetic liability can sum with that

contributed by the weak LQT alleles. Since the drugs that unmask the phenotype produce potassium channel block, similar to known LQT mutation, so presumably do the hidden unmasking liability alleles. The pharmacogenetic LQT syndrome is clinically quite important; causing the recall of several otherwise valuable drugs, and is now recognized as a potentially lethal side effect of many common medications. These include antihistamines, such as Seldane, antibiotics and cisapride, as well as the more predictable antiarrhythmics. Most of the implicated drugs share a common mechanism of action that involves the block of I_{Kr} potassium channels, and a number of cases now explicitly demonstrate that weak or subclinical alleles in the LQT genes, encoding both Na^+ and K^+ channels, are contributory to the pharmacogenetic disease.

A special consideration of pathogenic weak LQT alleles is raised by the contribution of these genes to sudden infant death syndrome (SIDS). In a landmark prospective study spanning an 18-year period, Schwartz and coworkers from nine large maternity hospitals performed EKGs on all healthy newborns between the third to fourth day of life, studying a total of over 34 000 neonates. At the 1-year follow-up evaluation, it could be observed that infants who had died of SIDS had a longer QTc interval *at birth* than did survivors or infants dying of other causes, even though none had a positive family history for LQT. Half of the infants dying of SIDS (12 of 24) had a QTc at birth greater than two standard deviations above the mean for the cohort, a finding that alone predicted greater than a 40-fold increase in the odds of dying of SIDS. However, because SIDS is so rare, despite the finding's dramatic odds ratio, only 2% of the neonates found to have a long QT die of SIDS. More recent studies have begun to add a molecular dimension to these cases, and for a few cases, a new mutation in one of the LQT genes, producing an allele previously seen in a family with the classical syndrome, can be identified. It remains to be determined whether weak inherited mutations, or even polymorphisms, in two or more of the LQT genes contribute to the rest.

6
Ion Channel Diseases of Muscle

6.1
Function of Ion Channels in Muscle

In many ways, the skeletal muscle AP is similar to the initial and final portions of that in the heart, but lacks the long plateau phase (Fig. 7). It is a fast depolarization, driven by sodium and calcium currents, followed immediately by a rapid repolarization driven by potassium currents, and in this regard is much like that of nerve (Fig. 1a). Instead of arising endogenously within the tissue, as at the cardiac sinoatrial node, the inciting muscle depolarization arrives *synaptically* via the quantal release of a chemical neurotransmitter, acetylcholine (ACh), from a motor nerve terminal bouton that forms a specialized neuromuscular junction with the *motor endplate* of the muscle plasma membrane, or *sarcolemma*. As the motor nerve's propagating AP reaches its terminus, cytosolic calcium rises, triggering a few hundred *synaptic vesicles*, each holding several thousand ACh molecules, to fuse into the presynaptic neuronal membrane (Fig. 9). As they fuse, each vesicle releases, in a quantal fashion, all its contents. This released ACh diffuses, in a matter of milliseconds, across the *synaptic cleft* to the muscle, where it is degraded by acetyl

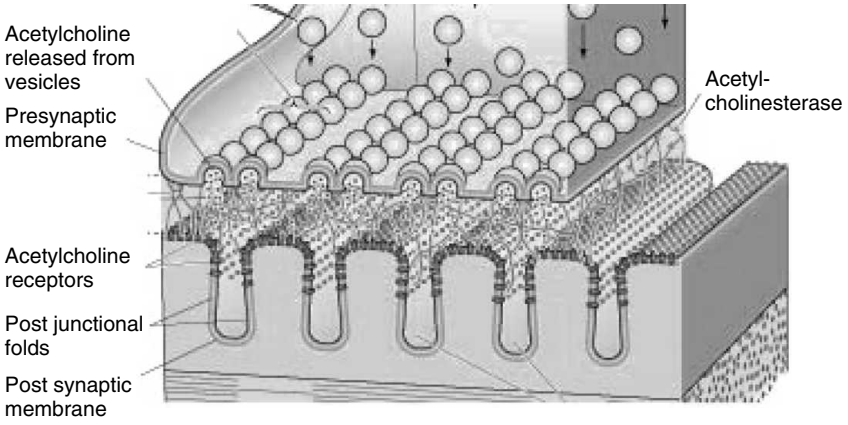

Fig. 9 Neuromuscular junction.

cholinesterase. A ligand-gated cation channel found on the postjunctional folds of the sarcolemmal endplate membrane, the heteropentameric nicotinic ACh receptor (nAChR), is activated by ACh binding (Figs. 5 and 9). Each receptor activated progressively brings about an initial incremental muscle membrane depolarization, and these events, referred to as *miniature endplate potentials* (MEPPs), were critical in uncovering the quantal nature of synaptic transmission. This receptor is the target of autoimmune and genetic myasthenia syndromes, and these quantal synaptic events are disturbed by these diseases, which are discussed below. In the physiological condition, a large number of tiny receptor-mediated MEPPs summate, producing an endplate potential that brings the membrane potential to the *threshold* at which a few sodium channels begin to open (Fig. 10). The sodium channels in turn further depolarize the membrane, causing more adjacent sodium channels to open in a reinforcing cycle until all sodium channels in the muscle have explosively opened while rapidly spreading a depolarizing wave across the surface of the muscle. At this point, all of the sodium channels are rendered ''inactive'' and nonexcitable, beginning the process of repolarization, a process completed when more slowly activating potassium channels restore the resting potential and return the sodium channels to the ''closed'' state. Unlike the situation in cardiac muscle, the rapid recovery of skeletal muscle excitability allows rapid repetitive contractions, an advantage in performing fine precision movements. The major subunit of muscle sodium channels is the muscle-specific isoform α_4, encoded by *SCN4A*, a relative of the gene involved in *LQT3*. Alleles of this one gene produce the diverse array of muscle phenotypes that will be discussed below.

As the depolarization wave of the muscle AP spreads across the sarcolemmal plasma membrane, it extends into specialized membrane invaginations, called *T-tubules*, which dive deep into the cytoplasm and ramify near the contractile proteins (Fig. 9). Their function is to facilitate calcium-dependent activation of contraction throughout the large muscle fiber. In the muscle T-tubule, as in the motor nerve bouton, the depolarization wave activates the voltage-gated calcium channel, which is similar in structure to

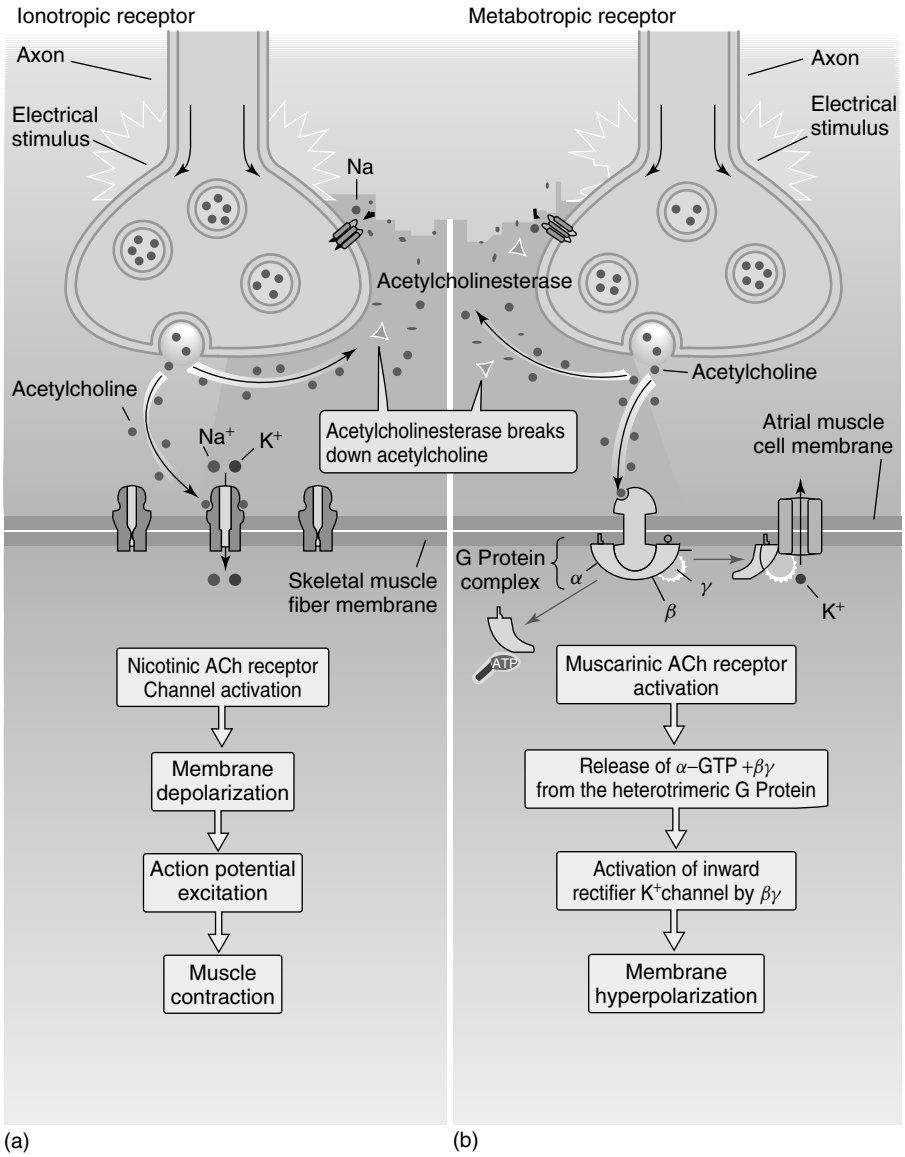

Fig. 10 Mechanisms of acetylcholine receptor activation.

the sodium channel, discussed above. The major, α_1, subunit is pseudotetrameric and contains the ion-conducting pore. Its function is modified by auxiliaryβ, γ and α_2/δ subunits, the skeletal muscle calcium channel's isoforms being encoded by *CACNA1S, CACNB1, CACNG1*, and *CACNA2D1*, respectively (Fig. 5). This channel is responsible for rapidly immersing the contractile proteins throughout the large muscle cell in elevated concentrations of ionized calcium, thereby

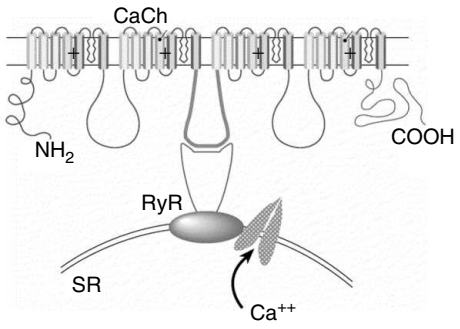

Fig. 11 Ca channel and Ryanodine receptor.

bringing about concerted contraction, much as was described for the cardiac contractile machinery. It does this in part by allowing the passage of extracellular calcium through its pore, down its electrochemical gradient into the cytoplasm. But additionally a large cytosolic loop in the skeletal muscle α_1-subunit contacts a *different* calcium channel located in a closely opposed *different* membrane compartment, the sarcoplasmic reticulum (SR) (Figs. 5 and 11). The SR membrane contains calcium pumps that rapidly sequester intracellular calcium after each AP, creating a releasable calcium store and restoring muscle relaxation. Through the physical interaction with its cytosolic loop, the voltage-gated calcium channel directly gates the SR calcium release channel. The release channel is called the *ryanodine receptor*, encoded by *RYR1*, and opening it spills the SR intracellular calcium stores into the cytoplasm. After activation, both the sodium and calcium voltage-gated channels spontaneously enter the nonconducting ''inactive'' conformation, beginning the process of membrane repolarization, a process completed by potassium channels that hyperpolarize the membrane, resetting the sodium and calcium channels into the ''closed'' conformation. The sodium and calcium channels then are kept closed by the large stabilizing current of the chloride channels, encoded by *CLCN1* (Fig. 5).

6.2 Ion Channel Dysfunction in Paralysis and Myotonia

The two major skeletal muscle phenotypes produced by ion channel disorders reflect either an inability to contract the muscle, ranging from weakness to *paralysis*, or an inability to relax the muscle, *myotonia*. While a third muscle phenotype, malignant hyperthermia (MHS), appears quite different, it is surprisingly closely related to the paralysis syndromes, in fact, being allelic. Two major themes in the ion channel diseases begin to develop in discussing the skeletal muscle diseases. First, it becomes clear that the LQT syndrome provides a powerful paradigm for understanding the types of alleles that produce disease and the mechanisms by which they act. Second, the proclivity of certain ion channel gene families to produce disease begins to emerge as does their ability to produce distinctly different clinical phenotypes with subtly differing alleles (Table 1).

While the pathophysiology of paralysis and hyperthermia is complex, that of myotonia is fairly straightforward. Since the high chloride conductance of *CLCN1* in the muscle membrane serves to stabilize

Tab. 1 Channelopathy gene families.

Gene family	*Tissue*	*Disease phenotype*	*Pathogenic mutation*
KCNE1	Heart/ear	LQT5/JLN	Dominant negative/recessive loss-of-function
KCNE2 (100%)[a]	Heart	LQT6	Dominant negative
KCNE3	Muscle	HOKPP	Dominant negative
KCNQ1	Heart/ear	LQT1/JLN	Dominant negative/recessive loss-of-function
KCNQ2	CNS	BFNC1	Dominant loss-of-function
KCNQ3 (80%)[a]	CNS	BFNC2	Dominant loss-of-function
KCNQ4	Ear	DFNA2	Dominant missense
KCNQ5	CNS	6q14	
RYR1	Muscle	MHS1	Missense
RYR2 (66%)[a]	Heart	Ventricular tachycardia	Missense
RYR3	CNS	15q14	
SCN1A	CNS	GEFS + /SMEI	Gain-of-function/loss-of-function
SCN2A	CNS	GEFS+	Gain-of-function
SCN3A	CNS	2q24	
SCN4A (40%)[a]	Muscle	HYPP/HOKPP/MHS/etc.	Gain-of-function
SCN5A	Heart	LQT3/Brugada S	Gain-of-function
SCN6A and *SCN7A*	Neuronal	2q23	
SCN8A	Motor endplate	12q13	
SCN9A	Neuroendo	2q24	
SCN10A	Nerve/muscle	3p22	
SCN11A and *SCN12A*	Sensory neurons	3p24	
SCN1B	CNS	GEFS+	Gain-of-function
SCN2B	Neuronal	11q23	
CACNA1S	Muscle	HOKPP/MHSS	Missense
CACNA1A	CNS	FHM1/EA2/SCA6/seizures	Many types
CACNA1F	Retina	Night blindness	Hemizygous loss-of-function
CHRNA1	Muscle	SCCMS	Gain-of-function

[a] Percent of gene family members already associated with disease.

the membrane potential, thereby preventing "echo" contractions after an induced contraction, its functional loss is associated with the inability to normally relax the muscle, and hence the slow muscle relaxation and muscle stiffness of myotonia. Both dominant and recessive mutations of this gene, which decrease channel current, produce myotonia and a characteristic "dive bomber" EMG record of repetitive contractions. The repetitive volleys of contraction can arise in skeletal muscle because unlike in the heart, where sodium channels are held in the inactive state for

a prolonged period to prevent arrhythmia, in skeletal muscle, sodium channels must be ready to accept a rapid train of controlled activations from the motor nerve. Problems arise, however, in the absence of a strong chloride stabilizing current, since instability of the membrane potential during recovery from a depolarization leaves a high probability that a secondary ''echo'' depolarization will reach threshold and trigger a repeated activation of the sodium channels.

The recessive loss-of-function alleles of *CLCN1* produce Becker myotonia, with a phenotype characterized by stiffness that warm-up exercise improves, and paradoxically weak hypertrophied muscles. The dominant-negative alleles leave more residual current and produce Thomsen myotonia, having a similar but milder phenotype without weakness. The hypertrophy arises because the muscles are constantly ''exercising'' even at rest secondary to their electrical instability, and the weakness arises because of incomplete recovery from sodium channel inactivation, as will be described for the periodic paralysis syndromes below.

6.3 Periodic Paralysis Syndromes

To understand how the array of periodic paralysis syndromes arise, it is essential to understand how very subtle ''tweaks'' in sodium channel function give rise to macroscopic phenotypes that are quite distinct – superficially the antithesis of one another – yet are so closely related that a given patient can transition from one state to the other. All of these pathogenic muscle sodium channel alleles appear to share with the cardiac sodium channel *LQT3* alleles a dominant gain-of-function mechanism of pathogenesis – *delayed and incomplete inactivation*. The essential biophysical feature of sodium channel function that makes this interpretable is the fact that while a depolarization will make it more probable that the voltage-sensitive gate of the closed channel will open, when sustained, depolarization also leaves behind more of the channels in an ''inactive'' nonexcitable conformation. As the sodium channel is the major mechanism for propagating APs in muscle (as it is in most tissues), this delicate balancing act has the potential to move these tissues from a state of hyperexcitability to a state of inexcitability, manifested as weakness and paralysis. Plasma potassium levels are commonly altered during these attacks of paralysis, and, while incompletely understood, probably has to do with the fact that the vast majority of the potassium in the body, >95%, is found in the muscle. The anxiety that surrounds clinical management of such changes is that very small amounts of potassium dramatically change the plasma potassium concentration and this is a critical determinant of the potassium Nernst potential (hence the membrane potential of all cells) and such changes in the heart pose the risk of fatal arrhythmia.

The ranges of phenotypes gain-of-function *LQT3*-like incompletely inactivating *SCN4A* alleles produce include: (1) hyperkalemic periodic paralysis (HYPP), (2) hypokalemic periodic paralysis (HOKPP), (3) paramyotonia congenita, a cold exacerbated myotonia and (4) potassium-activated myotonia.

HYPP alleles are the most common, and the disorder is characterized by short, mild frequent attacks of profound weakness beginning in infancy and provoked by rest just after exercise or stress. Commonly, the individual performs significant physical exertion, then sits to rest and finds he is unable to move for an hour

or more (although respiration is not compromised). There is often myotonia between attacks. During an attack, plasma potassium levels rise to pathological levels, probably via release from the depolarized muscle. The alleles are characteristically missense mutations altering amino acids in the transmembrane spans of the channel protein. Andersen syndrome, discussed above as caused by *LQT7* alleles, additionally has the muscle phenotypes of HYPP and that of MHS, discussed below, suggesting an intrinsic relation between the two. Furthermore, some HYPP alleles of *SCN4A* additionally produce MHS, and the gene is probably also the *MSH2* locus, a rare cause of the phenotype.

HOKPP is characterized by an onset in the second decade of infrequent, profound painless episodes of weakness that can last for days. During an attack, the plasma potassium can fall to dangerous levels, presumably being driven into the muscles. The factors known to incite the attacks are known to physiologically have this activity. They include insulin or glucose intake (which stimulates insulin release) and the hormonal changes that occur upon awakening. Two other loci, *CACNA1S* and *KCNE3*, also have alleles that produce HOKPP. Missense dominant alleles of *CACNA1S*, encoding the major α_1, subunit of the muscle voltage-gated calcium channel, were the first recognized and remain the most common cause of hypokalemic periodic paralysis. Most recently mutations in one of the skeletal muscle potassium channels involved in the rapid repolarization of the membrane, encoded by *KCNE3*, a relative of the *LQT5* and *LQT6* genes also have been shown to cause HOKPP. With this discovery, all of the members of the fully ascertained *KCNE* gene family are proven pathogenic loci, suggesting such familial relationships may be useful in promoting candidate genes for evaluation in disease association (Table 1).

6.4 Malignant Hyperthermia

The pathophysiology of malignant hyperthermia is typical of a pharmacogenetic syndrome; it involves an inciting agent, typically an inhalation anesthetic such as halothane, and an individual with a predisposing genotype. The pathogenic mechanism arises from a dramatic rise in muscle cytoplasmic calcium as the hypersensitized SR stores are discharged. This then secondarily produces contracture of the muscles and a hyper-metabolic state of glycogenolysis, ATP depletion, and lactic acidosis driven by the attempt to resequester calcium. This process evolves to produce hyperthermia (not fever) from activity of the contractile machinery and mitochondrial respiration, and disruption of the muscle membranes, releasing myoglobin, creatine kinase, and potassium, and leading to renal failure, disseminated intravascular coagulation and death The predisposing genotypes enhance the sensitivity of the calcium release process, which primarily involves the sarcolemmal calcium channel and the SR calcium release channel. Missense alleles altering either the cytosolic loop of the *CACNA1S*-encoded α_1 calcium channel subunit or its contact domains on the ryanodine receptor render this complex hypersensitive and capable of triggering massive calcium release, muscle activation, and malignant hyperthermia (Fig. 11). Over 50% of the cases are caused by dominant *MHS1* alleles of *RYR1* and the next most common cause is dominant *MHS5* alleles of *CACNA1S*. Some of the HYPP alleles of *SCN4A* additionally seem

to produce this syndrome, and it probably reflects *MHS2*. Three other *MHS* loci have been mapped but susceptibility alleles have yet to be identified. Additionally, this phenotype is also a component of Andersen syndrome, discussed above, affecting the potassium channel that controls the resting membrane potential in muscle and heart, *KCNJ2* (Fig. 8). Finally, alleles of *RYR1* also cause central core disease (CCD), a congenital myopathy characterized by nonprogressive proximal muscle weakness and distinctive muscle fiber histology. While individuals with CCD do have a susceptibility to anesthetic-induced MHS, the remainder of the disease phenotype is constitutive and does not require pharmacological induction, and therefore the disorder is illustrative of the continuum between genetic and environmental disease.

6.5 Other Monogenic Muscle Ion Channel Syndromes

Dominant gain-of-function mutations in four of the five subunits that compose the nAChR found at the neuromuscular junction and encoded by *CHRNA1*, *CHRNB1*, *CHRND* and *CHRNE* produce slow-channel congenital myasthenic syndrome (SCCMS), a phenotype characterized by muscle weakness. Acetylcholine dissociates slowly from these mutant receptors, leaving them persistently activated, depolarizing the membrane. One might guess that the prolonged receptor activation the mutant alleles produce will give a hyperexcitable muscle; however, as was discussed above in the periodic paralysis syndromes, the phenotype seen is produced by the loss of sodium channels into the inactive state in this chronically depolarized tissue.

6.6 Autoimmune Channelopathies in Muscle

Myasthenia gravis (MG) is one of the classic autoimmune diseases, first placed on a molecular footing in the early 1970s, well before the era of the monogenic channelopathies. It develops in mid-life, produces facial, respiratory, and limb muscle weakness and is associated with tumors of the thymus and antibodies to the nAChR. It is clear that the antibodies produce the disease, since they can passively transfer the symptoms and their removal is therapeutic. The autoantibodies accelerate the destruction of the nAChR, reducing their abundance in the synapse and hence the efficacy of synaptic transmission. This was first observed as a decrease in the size, but not number, of MEPPs, suggesting that the ACh-filled vesicles were normally releasing quanta of neurotransmitter, but that they had a smaller postsynaptic effect, causing weakness. Enhancing the synaptic concentration of ACh by inhibiting acetyl cholinesterase rapidly improves strength, and is used diagnostically and therapeutically (Fig. 9). Note that the muscle phenotype is very similar to that created by SCCMS alleles of the nAChR subunit genes, discussed above, but that those genetic syndromes do not have thymus tumors or autoantibodies, confirming that receptor dysfunction does not cause those findings in MG, the tumor appearing to be primary and causal in autoimmunity.

Lambert-Eaton myasthenia syndrome (LEMS) is another autoimmune disorder that produces a clinical picture very similar to that of MG, but preferentially targeting proximal limb muscles and being associated with small-cell carcinoma of the lung. It additionally produces symptoms referable to the autonomic nervous

system, such as dry mouth, so it is clear that the epitope targeted by the antibodies is not strictly limited to muscle. In fact, the antibodies are directed at the P/Q-type voltage-gated calcium channels of the presynaptic neuron. This channel is encoded by *CACNA1A* and is similar to its family members expressed in heart and skeletal muscle, but it participates in excitation-*secretion* coupling (not EC coupling), serving as a calcium entry pathway that couples the propagated AP to the biochemical pathways underlying neurotransmitter release at the presynaptic bouton, to be discussed below. It is distinguished from its family members by its high affinity for ω-conotoxin. Antibodies do not cross the blood-brain barrier, so symptoms in the autoimmune disorders are confined to effects in the periphery. As will be seen below, very different symptoms arise from genetic lesions in *CACNA1A* where CNS symptoms predominate.

7
Ion Channel Diseases of Nerve

7.1
Function of Ion Channels in Neurons

The neuronal AP is very similar to that of muscle: typically, activation is initiated across a *synapse*, neuroreceptors and their endogenous or coupled channels are activated, the supra-threshold summated postsynaptic currents in turn trigger a rapidly spreading depolarization wave by voltage-gated sodium and calcium channel currents, this is rapidly followed by a repolarization driven by potassium currents, and the AP couples to biochemical effector pathways through a rise in the cytosolic calcium concentration. Despite this gross oversimplification of all of the diversity of neuronal structure and function, and their vastly more complex geometry, the major distinctions from muscle lie at the afferent and efferent ends of the neuronal transduction pathway, not in the propagated AP in between.

First, neurons have a vastly more complex variety of activating, as well as inhibitory, neuroreceptors and synapses than muscle, and they are primarily found at the branching *dendritic*, or afferent, ends of the prototypical neuron (Fig. 12). The receptors produce both depolarizing, excitatory, as well as hyperpolarizing, inhibitory, *postsynaptic potentials* (EPSPs and IPSPs) that, like the MEPPs of muscle, summate over time, but also through the complex spacial geometry of the arborized dendritic tree. This summation serves the ''computational'' function of the neuron; some combinations of dendritic inputs will drive the soma, or neuronal cell body, to initiate an AP that is propagated down the axon, while others that differ slightly in timing, spacial geometry of the activated synapses, or the mix of incoming neurotransmitters will not.

Second, when the neuron does ''decide'' to produce a propagated AP, the elevated cytosolic calcium wave does not participate in EC coupling, but rather in excitation-secretion (ES) coupling, the controlled release of neurotransmitter into another synapse (Fig. 10), as was briefly discussed for LEMS, above. In the neuron, the calcium-coupled neurosecretion events occur after the AP has been conducted down the *axon*, the long cellular projection that serves as the efferent and effector side of the neuron. There a wide variety of small-molecule neurotransmitters can be released into a synapse to initiate in the downstream neuron the process just described above (Fig. 12).

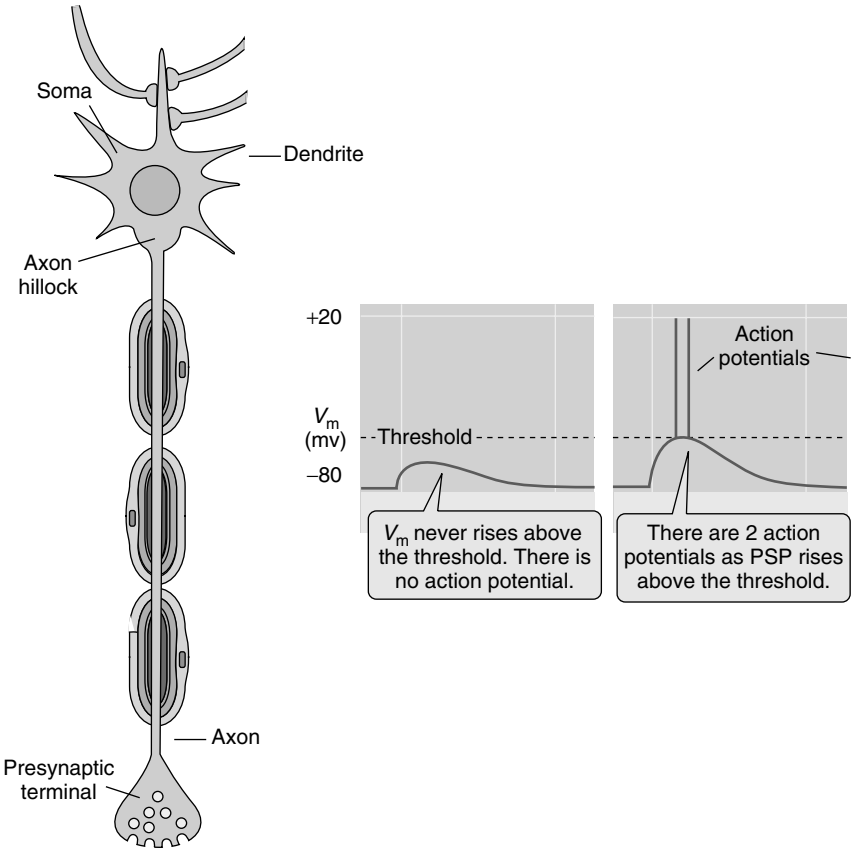

Fig. 12 Neuron structure and initiation of neuronal AP.

7.2 Ion Channel Dysfunction in Seizures

As opposed to the situation in heart and muscle, synchrony of electrical activity in the CNS is actively prevented. An abnormally synchronous discharge of neurons in the CNS produces a *seizure,* a pathological state characterized by a stereotyped alteration in behavior. Seizures are the most common monogenic ion channel phenotype in the CNS and in many ways are similar to the arrhythmia phenotype that arises in the hyperexcitable LQT heart. Both are periodic disorders in constitutionally hyperexcitable tissues in which the normal rhythmic electrical activity of the tissue is temporarily lost. However, whereas the heart is typified by its extremely homogeneous set of responding cells, the CNS displays maximal tissue complexity both in terms of the number of different cell types present and in the number of different ways they connect with and influence one another in stimulatory or inhibitory fashions. Therefore, while one can visualize the very specific and individual contribution each channel type makes to components of an action potential perturbed in LQT in the heart or in the skeletal muscle syndromes, one can much less specifically interpret how

Tab. 2 Unlike heart, must still guess WHERE neuronal channels act.

Seizures:		
BFNC1	*KCNQ2*	Haploinsufficiency, decrease I_K
BFNC2	*KCNQ3*	Haploinsufficiency, decrease I_K
ADNFLE	*CHRNA4*	GOF increase activation, increase I_{Na}
ADNFLE	*CHRNB2*	GOF increase activation, increase I_{Na}
GEFS+	*SCN1B*	GOF decrease inactivation, increase I_{Na}
GEFS+	*SCN1A*	GOF decrease inactivation, increase I_{Na}
GEFS+	*SCN2A*	GOF decrease inactivation, increase I_{Na}
GEFS+	*GABRG2*	Dominant missense, decrease I_{Cl}
JME	*GABRA1*	Dominant missense, decrease I_{Cl}
JME	*CACNB4*	Dominant missense, I_{Ca}
SMEI	*SCN1A*	Haploinsufficiency, decrease I_{Na}
. . .[f]	*KCNA1*	Haploinsufficiency, decrease I_K
. . .[f]	* *CACNA1A*	Dominant negative, decrease I_{Ca}
Ataxia		
. . .[f]	* *CACNA1A*	Dominant negative, decrease I_{Ca}
SCA6	* *CACNA1A*	Dominant CAG expansion, decrease I_{Ca}
EA2	* *CACNA1A*	Haploinsufficiency, decrease I_{Ca}
EA1	*KCNA1*	Haploinsufficiency, decrease I_K
Migraine:		
FHM1	* *CACNA1A*	Dominant missense, decrease I_{Ca}
FHM2	*ATP1A2*	Dominant loss-of-function

f – case reports, discussed in text.

or even where the channel dysfunction underlying seizures occurs. Also, rhythm disorders in the heart are often a once in a lifetime event; in the CNS they are usually a lifelong chronic condition, *epilepsy*. Epilepsy is also a useful phenotype to serve as a springboard to understanding the other major monogenic CNS channelopathy phenotypes, *ataxia* and *migraine*, as they can be allelic.

While the complexity of neuroanatomy obscures functional analysis of the mutations causing monogenic epilepsy syndromes, extrapolation from the cardiac and muscle syndromes provides a simplified predictive framework of molecular pathology: K^+ and Cl^- channels, which physiologically stabilize excitable tissue, will likely have pathological lesions that diminish their current, and Na^+ and Ca^{++} channels, which physiologically excite the tissue, will likely have gain-of-function lesions (Table 2).

7.3 Hereditary Epilepsy Syndromes

Nearly 40% of all epilepsy is associated with no macroscopic pathological lesion, and is therefore classically referred to as *idiopathic epilepsy*, a common disorder that affects $\sim 1\%$ of the population. It is overwhelmingly a genetic disease, with monozygotic twins greater than 95% concordant for the phenotype; however, nearly all cases are polygenic and most of

those genes still remain to be identified. Obviously, since ion channels control electrical activity in the CNS, as in the heart and muscle, they are strong functional candidates for this disorder. In man, they were the first identified, and remain nearly the exclusive, proven genetic causes of epilepsy. Only a handful of rare monogenic epilepsy syndromes are recognized, but predictably success at pathogenic allele definition has thus far come only from these rare monogenic syndromes.

7.4 LQT-like Loci and Alleles in Neuronal Syndromes

The first rare monogenic seizure syndrome for which the major etiological genes were identified was benign familial neonatal convulsions (BFNC), a rare autosomal dominant disorder characterized by a brief period of seizures in the neonatal period, generally resolving in weeks, but 10% having persistent adult epilepsy. The BFNC loci were mapped to chromosomes 20 and 8. The *BFNC1* gene was positionally localized within chromosome 20q13.3 taking advantage of a family with the syndrome and a microdeletion chromosome. The interrupted locus contained a promising candidate gene, *KCNQ2,* a member of the *LQT1* gene family that was predominantly expressed in neurons. Unlike the *LQT1* alleles that demonstrate dominant-negative interactions *in vitro,* this first *BFNC1* allele was a null, and most subsequent alleles are simply loss-of-function. The relevant neuronal currents mediated by this channel must be so critically tuned that pathogenic alleles can achieve dominance simply via haploinsufficiency. Heterozygous null mice display a milder inducible pharmacogenetic syndrome, showing no basal seizures, but only an increased sensitivity to seizure-inducing drugs. Presumably, the strain's polygenic background raises their seizure threshold making them appear much like silent-carrier family members of the ''sporadic'' LQT syndrome probands who have disease produced by weak alleles.

Since the *KCNQ* family had the demonstrated ability to produce disease, other family member genes were sought by homology. *KCNQ3* was thus identified, and mapping to chromosome 8q, was a tempting candidate for the second BFNC locus, a hypothesis proven by finding loss-of-function alleles segregating in a family. While both KCNQ subunits produced channels when expressed *in vitro,* neither subunit alone produced a recognizable current. However, KCNQ2 and KCNQ3 were subsequently recognized to heteromultimerize to form the ''M current,'' a long-sought signature potassium current activated by muscarinic acetylcholine receptors (mAChR) (Fig. 10). Therefore, both their gene-family relationship and their functional subunit interaction help explain the common phenotype that mutations in either gene produce. The final member of this *KCNQ* family, *KCNQ5,* mapping to chromosome 6q14, and the only member still to be associated with a disease, is expressed in neurons and can also interact with KCNQ3 to produce M current, making it an extremely strong functional candidate disease gene.

7.5 Other Monogenic Ion Channel Epilepsy Syndromes

The gene *CHRNA4* was the first ion channel gene demonstrated to contribute pathogenic alleles to an epilepsy syndrome. It is found on chromosome 20q13 and encodes the most abundant neuronal

isoform of the major subunit, α_4, of the nAChR. Unlike the mAChR, discussed immediately above, which couples to channel gating via G-protein activation (a G-protein coupled receptor, GPCR), the nAChR, like that found in muscle, is a heteropentameric receptor/channel that is *itself* a ligand-gated nonselective cation channel, its activation depolarizing the membrane (Fig. 10). It is closely related to the muscle nAChR, which participates in the phenotype of SCCMS congenital myasthenia. In the nerve, it is composed of two α- and three β-homologous subunits, each with four transmembrane α-helices (Fig. 5). The rare seizure syndrome, autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE), producing a phenotype with brief clusters of frontal seizures that occur at night, was mapped to this region in a family and missense alleles identified. To date, three alleles have been recognized, all altering the channel pore region and receptor function but having no obvious common effect on *in vitro* channel behavior. More recently, mutations in the most abundant neuronal β-subunit, β_2, were also recognized to cause this syndrome, suggesting that the channel isoform relevant to this phenotype is an $\alpha_4\beta_2$ pentamer. These missense alleles in *CHRNB2*, located on chromosome 1q21, produced the common *in vitro* effect of receptor activation, suggesting that some depolarizing gain of function is probably the mechanism of dominant pathogenesis, like that found in the SCCMS muscle pathogenic homologs. The vulnerable cell in the CNS whose function is perturbed by these mutations, however, remains to be defined.

Fever, a common accompaniment of many illnesses, lowers the seizure threshold so it is not surprising that febrile seizures are by far the most common polygenic seizure disorder, affecting 3% of children worldwide. While these susceptibility genes remain to be defined, a rare Mendelian dominant seizure syndrome that includes febrile seizures provides the first lead to their identification. This febrile seizure syndrome additionally evolves to include a variety of afebrile seizures, and is called *generalized epilepsy with febrile seizures plus* (GEFS+). The first locus responsible for GEFS+ was mapped in a large family to chromosome 19q13.1 and a missense mutation was identified in an auxiliary subunit of the voltage-gated sodium channel. This subunit, the β_1 subunit encoded by the gene *SCN1B*, has a single transmembrane helix and functions only to modify the activity of the large α-subunit (Fig. 5). Subsequently, mutations producing GEFS+ or closely related syndromes were identified in two different adjacent neuronal sodium channel α-subunit genes, *SCN1A* and *SCN2A*, on chromosome 2q24. Not until the α_1 subunit alleles were coexpressed with their auxiliary β-subunits did a reproducible picture of defective channel inactivation and sustained sodium current appear. This is a picture similar to that observed with the *LQT3* and HYPP and HOKPP alleles of the gene-family members *SCN5A* and *SCN4A*, respectively. As in the heart, most simply, a persistent sodium channel current can be viewed as a gain-of-function dominant lesion that favors a hyperexcitable state; however, the periodic paralysis lesions caution that hyperexcitability can easily transition into inexcitability, through the inactivation mechanism, and this dichotomous nature of sodium channel lesions is reinforced by the recent observations that a rare, very severe dominant seizure syndrome, initially associated with febrile seizures, called *severe myoclonic epilepsy of infancy* (SMEI), proved to be allelic with GEFS+. All of

dozens of known alleles were shown to be new mutations in *SCN1A*, and their nature (e.g. frameshift, nonsense) suggests they are predominantly functional nulls. While the physiological interpretation of these findings is clear, together they are puzzling; haploinsufficiency for the major subunit of the sodium channel produces a very severe dominant *loss*-of-function phenotype via some critically tuned cell type; a milder syndrome being caused by the dominant *gain*-of-function GEFS+ alleles.

The remaining GEFS+ locus, *GABRG2*, found within a cluster of GABA receptor genes on chromosome 5q31, encodes the γ_2 subunit of the inhibitory $GABA_A$ receptor. The $GABA_A$ receptor, like the nAChR discussed above, is a pentameric ligand-gated channel, but it differs in that instead of conducting a depolarizing cationic current, it conducts a stabilizing chloride current (Fig. 5). This receptor is the major mechanism through which GABA, the principle *inhibitory* neurotransmitter in the brain, functions. It is at this site that the benzodiazepine drugs act to treat seizures, by potentiating GABA effects, and that toxins, such as picrotoxin, act to induce seizures, by blocking GABA. So physiologically the inhibitory, neuronal silencing, activity of GABA participates in preventing seizures. The GEFS+ allele produces a decrease in GABA-induced chloride current *in vitro*. Therefore, like the seizure-inducing toxins, seizure-inducing mutations alter receptor/channel function to produce *less* GABA-induced stabilizing current.

While some human ''seizure'' genes have not recapitulated that phenotype in mice (for instance, mice homozygous for null alleles of *CHRN4A* and *CHRNB2* – the two loci thus far recognized with alleles causing ADNFLE in man – have a phenotype that alters the pain response, not seizures), spontaneous mutations producing a seizure phenotype in mice have led to the recognition of an important new category of ion channel seizure disorders in man, those altering voltage-gated calcium channel function. More importantly, those loci have proven to be particularly informative for their ability to tie the various neurological phenotypes together in an interpretable fashion. As discussed above, the voltage-gated calcium channels are similar to the voltage-gated sodium channel, and the major pore-containing α_1 subunit that dictates the channel's subtype is pseudotetrameric with its function modified by the auxiliary β, γ, and α_2/δ subunits (Fig. 5). Alleles in all four different types of neuronal voltage-gated calcium channel subunit genes produce a monogenic absence seizure phenotype in mice. The ''lethargic,'' ''stargazer,'' and ''ducky'' mice are recessive phenotypes produced by mutations altering neuronal calcium channel auxiliary subunits, *CACNB4* encoding a β-subunit, *CACNG2* encoding a γ-subunit, and *CACNA2D2* encoding a protein cleaved to produce the α_2 and δ-subunit, respectively. Of these three genes, a human phenotype has been reported only for mutations in the first. The human *CACNB4* gene maps to human chromosome 2q22-q23 and two dominant alleles, a truncation and missense allele, were found in families with a dominant seizure syndrome. The human *CACNG2* maps to chromosome 22q13.1 and the human *CACNA2D2* gene maps to 3p21.3, both remaining only promising seizure candidate genes in man. The ''tottering'' and ''leaner'' mice are recessive seizure phenotypes produced by alleles of *CACNA1A*, the gene encoding the major α_1 subunit of the neuronal P/Q-type calcium channel. The P/Q-type calcium channel plays a major

role in calcium entry underlying synaptic release of the major *excitatory* neurotransmitter, glutamate, and while this process is decreased in the mutants, suggesting they are hypomorphic alleles, it is unclear how this produces a hyperexcitable seizure phenotype.

7.6 Monogenic Ataxia and Migraine Syndromes

While the ''tottering'' and ''leaner'' mice are recessive seizure phenotypes produced by alleles of *CACNA1A*, a seizure phenotype is *not* the major phenotype caused by mutations in this gene in man. Human mutations in *CACNA1A*, which maps to chromosome 19p13, have been shown to cause three apparently distinct and different late-onset neurological disease phenotypes: episodic ataxia type 2 (*EA2*), familial hemiplegic migraine type 1 (*FHM1*), and spinocerebellar ataxia type 6 (*SCA6*). The *EA2* alleles are predominantly truncations, with over 22 known alleles, including frameshift and splice site mutations, but also five missense alleles, some altering conserved pore residues producing complete loss of function. It is therefore presumably a haploinsufficiency dominant loss-of-function syndrome. Familial hemiplegic migraine is caused by at least nine known missense alleles producing no obvious uniform functional change in calcium current *in vitro*; therefore, the relevant functional change they share in common is presumably subtle. Finally, SCA6 is a progressive degenerative phenotype primarily caused by trinucleotide expansion alleles. The polymorphic CAG repeat encodes a C-terminal polyglutamine repeat of 5 to 20 residues in unaffected individuals. Pathogenic alleles encode 21 to 30 glutamines. The only point mutant allele recognized to produce the syndrome is G293R, which changes a conserved pore residue. An intermediate-length CAG repeat allele with only 20 repeats produced the milder phenotype of EA2.

Thus, the four allelic *CACNA1A* diseases in man and mouse are clearly closely related at the molecular level. The phenotypes also can blend one into the other, for instance, many individuals with FHM have ataxia as do most of the murine seizure mutants, and recently a dominant-negative truncation allele has been reported to produce a syndrome of progressive ataxia and seizures in a child. In man, the mildest alleles appear to be the missense mutations producing FHM1. On a phenotypic continuum, these appear to be hypomorphic since the truncations, pore mutations, and intermediate repeat expansions produce EA2, apparently a haploinsufficiency syndrome. Expanding the polyglutamine repeat by only a few additional residues yields the potent long-repeat alleles producing the progressive SCA6 syndrome, which can also be produced by one specific missense pore mutation. While the mechanism of action of all pathogenic polyglutamine expansion alleles are controversial, if the three human *CACNA1A* phenotypes are truly the continuum suggested by the EA2 intermediate repeat phenotype, these repeat expansion alleles should be dominant negative to eliminate more of the P/Q current than haploinsufficiency and to keep the progression of allele potency parallel to the severity of the symptoms and pathology. While all of the human alleles produce the phenotype in heterozygotes, the mouse seizure alleles, which are missense, like FHM1, and demonstrated to be hypomorphic, produce no phenotype in heterozygotes, including knockout null alleles; decreased synaptic glutamate neurotransmitter release and

seizures being produced only in the homozygotes.

Another strong clue of the relationship between ataxia and seizures comes from the other known episodic ataxia locus, *EA1*. EA1 is produced by dominant loss-of-function alleles of perhaps the most ''famous'' potassium channel, ''shaker'', named after its mutant phenotype in fly, and the paradigmatic first K^+ channel cloned. It is a voltage-gated potassium channel formally called *KCNA1*. Knockout null alleles in the mouse produce a recessive seizure disorder, with the heterozygotes lacking a phenotype, just like the calcium channel mutants, but like them showing a reduced threshold for induced seizures, hinting at a potential mechanism for pharmacogenetic neurological syndromes in man. While the vast majority of EA1 patients have only ataxia, a few cases have been reported to additionally have seizures.

Just as examining both loci that produce episodic ataxia, *EA1* and *EA2*, informs the underlying pathophysiology of the indistinguishable diseases they produce, so too does examining both loci that cause familial hemiplegic migraine, *FHM1* and *FHM2*. Whereas *FHM1* alleles are subtle missense mutations of the calcium channel-encoding *CACNA1A* gene, recently *FHM2* alleles were discovered to be mutations in *ATP1A2*, the gene encoding the $\alpha 2$ subunit of the Na/K-ATPase, one of the major ion pump mechanisms responsible for establishing the ion gradients tapped by ion channels (Fig. 6). This is the first disease that is established to be caused by mutations in the Na/K pump, a central physiological mechanism. All FHM2 alleles identified to date are missense and alter narrowly conscribed domains of the pump protein. While loss-of-function and haploinsufficiency mechanisms are more suggestive of deletions and other forms of more readily produced null alleles than the observed constrained missense, this has been suggested to be the mechanism of some pathogenic alleles; however, detailed enzyme kinetics have more recently shown others to achieve dominance by gain of function, producing altered kinetics of the pump. It is still not clear what biophysical property of the neuron is perturbed in common by all of the FHM lesions, although a common denominator seems to be membrane depolarization and elevated cytosolic calcium.

7.7 Other Monogenic Neuronal Ion Channel Syndromes

One of the first monogenic CNS ion channel disorders for which the underlying pathogenic alleles were identified is the rare disorder hyperekplexia (HE), more commonly called *Startle syndrome*. The phenotype includes hypertonia and a severe startle reaction that simulates a drop seizure. It is produced by dominant and recessive mutations in *GLRA1*, the gene encoding the $\alpha 1$ subunit of the glycine receptor/channel. Since like the inhibitory GABA – and excitatory nAChR – receptor/channels, described above, the chloride-conducting inhibitory glycine receptor is a ligand-gated ion channel, sharing with other members of this channel family a subunit structure with four membrane-spanning helices and a characteristic heteropentameric composition (Fig. 5), it is not surprising that recessive mutations in the *GLRB* gene, encoding the glycine receptor β-subunit, also cause the same HE phenotype. Further, it is interesting that pathogenic alleles in all three types of ligand-gated channels, causing the discussed syndromes

of HE, SCCMS, ADNFLE, and GEFS+, are missense mutations primarily altering residues in the extracellular loop between the second and third transmembrane helix that controls gating, suggesting a related molecular pathogenesis of these macroscopically distinct diseases.

Many of the mutations that underlie hereditary defects in the special senses, such as vision and hearing, are found in ion channel genes. X-linked congenital stationary night blindness type 2 is caused by defects in the retinal-specific close relative of both the neuronal calcium channel "seizure-ataxia-migraine" gene *CACNA1A* and the skeletal muscle "HOKPP periodic paralysis" gene *CACNA1S*, discussed above. The syndrome is caused by several loss-of-function mutations in *CACNA1F*. Color vision requires, in addition to the three cone opsin pigment genes, mutations in which cause loss of color detected by one cone type, only the genes encoding the two subunits of a specific cyclic nucleotide-gated heteromultimeric ion channel found in the photoreceptor membrane (Fig. 5). Defects in these channel subunits cause color blindness due to dysfunction of all cones. Rod monochromacy is produced by at least 10 recessive missense alleles of *CNGA3* and Achromatopsia type 3 is produced by missense loss-of-function alleles in *CNGB3*.

Nonsyndromic deafness (NSD) is produced by mutations in dozens of genes, including those potassium channel genes that contribute alleles to produce Jervell and Lange-Nielsen recessive LQT syndrome, discussed above. Additionally, the genes encoding subunits of a very different type of channel, the connexin gap junctions (Figs. 5 and 13), are the most common source of alleles for NSD, being polymorphic in many populations. Gap junctions serve to connect all types of cells via a large nonselective pore that mediates the transit between cells of not only ions but also small macromolecules and metabolites. They are functionally dimers contributed by each member of a pair of cells, each cell membrane having a hexameric hemichannel that seals together with its partner. Each hemichannel is composed of the family of connexin subunits. Alleles of *GJB2*, encoding connexin 26, are the most common cause of NSD. There are a few dominant alleles, but several dozen recessive alleles, including one specific polymorphic pathogenic allele, 35delG, which accounts for as many as 4% of the European Caucasian alleles. Alleles of *GJB6* and *GJB3* also contribute to this syndrome. The mechanism by which they act appears to be similar to that of the Jervell and Lange-Nielsen LQT alleles; they perturb the formation of the potassium-rich endolymph fluid in the inner ear that is required for signal transduction. Curiously, some alleles of all three connexin genes also cause distinct hyperkeratotic skin syndromes with or without deafness.

7.8 Acquired CNS Ion Channel Syndromes

Just as cardiac failure produces an altered pattern of ion channel gene expression, and thereby creates an acquired channelopathy arrhythmia syndrome (see Sect. 5.7), experimental forms of induced temporal lobe epilepsy, the most common form of adult epilepsy, greatly reduce expression of the *KCND2* potassium channel gene, producing a downregulation of the neuronal A-type potassium current and a reduced threshold for seizure initiation in the hippocampus, a common origin for such seizures. Thus, seizure activity

produces a reduced threshold for subsequent seizures.

7.9 Polygenic Syndromes of Altered CNS Excitability

While most common seizure, migraine, and ataxia syndromes behave as complex polygenic traits, *not* as the simple monogenic Mendelian traits discussed above, and none of the genes involved in the polygenic forms of the disease have yet been convincingly demonstrated, a definition of the shared pathophysiology of these monogenic syndromes is likely to provide the best leads to the nature of those genes and to novel therapeutics for these common diseases. Likewise, while the definition of specific pharmacogenetic syndromes of altered neural excitability is only in its infancy, largely limited at this time to the definition of those individuals with altered rates of metabolism of seizure or antipsychotic medications, one would anticipate a dramatic impact on neuropsychopharmacology just by defining the genotypic basis of the wide variance now observed in patient response to current neuropsychiatric drugs. Additionally, it is likely that polygenic ion channel disorders produce a wider range of phenotypes in the CNS than those already revealed by the monogenic disorders. The salient feature of the CNS ion channel disorders, as well as those in the heart and muscle, was that they arose from a *periodic* disturbance in normal rhythmic activity. They were intrinsically episodic disorders, although many progressed to become constant. Many of the common complex polygenic neuropsychiatric disorders share this character. Further, several of the drugs used to treat the recognized channel phenotypes are additionally used to treat these disorders (e.g. valproate is used to treat both seizures and bipolar disease). Ion channel genes are thus important "functional candidates" to pursue within the broad chromosomal regions shown through linkage or linkage disequilibrium to be associated with these diseases, and are particularly intriguing should alleles be recognized that are similar in activity to those seen in the monogenic channel disorders.

8 Ion Channel Diseases of Epithelia

8.1 Structure and Function of Epithelial Tissues

Epithelia are sheets of *polarized* cells (sometimes consisting of many layers but only one cell layer of which is functionally significant) that participate in the transport of ions, water, and metabolites, not merely in and out of the cell, but fully *across* the entire cell sheet (Fig. 13). The epithelial cells are not excitable, like heart, muscle, and nerve, but they are electrically and metabolically coupled horizontally by gap junctions, described above, and the epithelial sheet therefore functions nearly as though it was two sheets of parallel membrane with cytosol between. One side of the epithelial sheet, called the *basolateral membrane*, faces the blood and is relatively unspecialized; the other, called the *apical membrane*, lines a nonblood compartment, often the lumen of a tubule, and the membrane is often elaborated into a brush border and microvilli (Fig. 13). It is primarily in the apical membranes that are found the many special channels and transporters that distinguish one epithelium from another. The point of demarcation between the two faces of

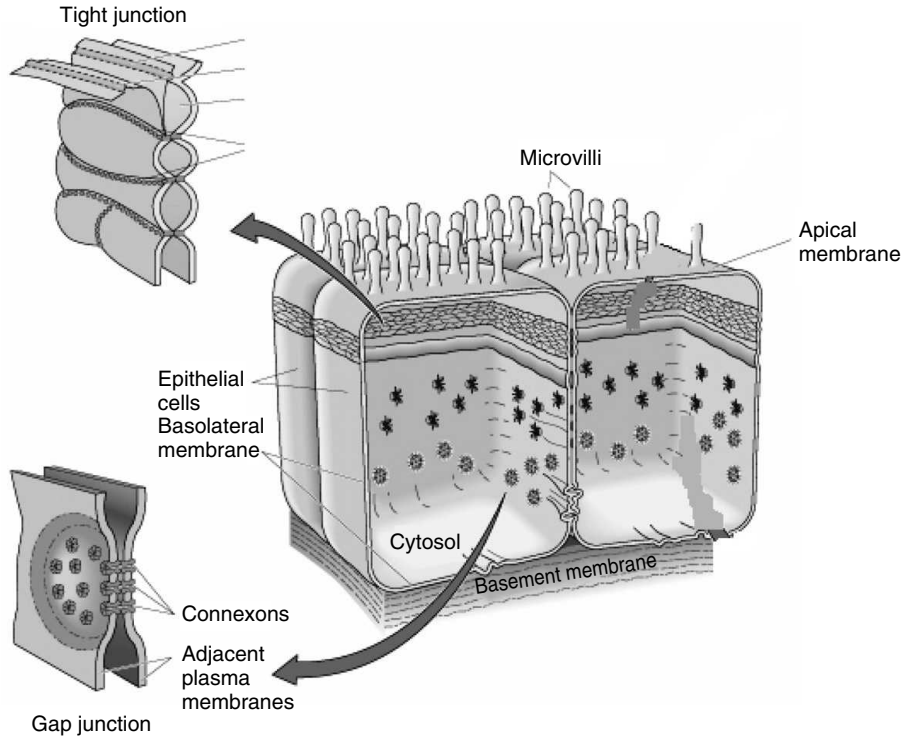

Fig. 13 Structure of epithelia.

an epithelial cell is the *tight junction*, the special barrier-forming connection made between adjacent cells in the epithelium (Fig. 13).

Epithelia serve two essential functions in physiology that can be perturbed in disease: to transport salt, water and other substances from one compartment to another, and to maintain gradients of salt, water, or other substances between compartments. While all epithelia share a fundamental organization and have in common a basic set of transport functions, various epithelia are optimized to perform one or the other of these two principle functions, and this is primarily conferred by the nature of the tight junctions between cells in the sheet. Those optimized for rapid transepithelial transport have ''leaky'' tight junctions and large *paracellular* pathways between cells providing a shunt parallel to the *transcellular* pathway across the sheet, and those optimized to form large electrical or chemical gradients across the membrane sheet have ''tight'' tight junctions that do not allow the passage of ions and water except through the cells.

8.2 Function of Ion Channels in Epithelia

Even though various epithelia transport a wide spectrum of compounds, there are a number of basic membrane properties that they all share, and these shared properties even extend to most nonpolarized mammalian cells, as introduced in Sect. 2. This

generalization is most particularly true for epithelial basolateral membranes, which are much less specialized and more like those of other cells. First there is a Na/K-ATPase ion pump located in the basolateral membrane (Figs. 6 and 14). This ATPase is oriented so as to extrude Na^+ from the cytoplasm in exchange for the uptake of K^+. Second, the electrical potential difference across the basolateral membrane is electrically negative (cell interior with respect to the blood) and on the order of 50–60 mV, like most mammalian cells. Third, the intracellular ion concentrations reflect the activity of the Na/K pump, with a high internal K^+, a low internal Na^+ and a Cl^- concentration near its Nernst electrochemical equilibrium potential (Fig. 6). Fourth, the passive permeability of the basolateral membrane is predominated by that for K^+, with low permeabilities to Na^+ and Cl^-. Since K^+ is not in electrochemical equilibrium across the K^+-permeable basolateral membrane, the −60 mV resting membrane potential is then a K^+ diffusion potential attenuated by low finite Na^+ and Cl^- permeabilities. Finally, the properties of the apical membrane of epithelia are very diverse, but commonly are predominated by a high Na^+ permeability. The specifics of these apical Na^+ permeabilities and their properties, however, vary such that broad generalizations can not be made. Major breakthroughs in understanding epithelial function occurred as Ussing defined how simply opening a passive Na^+ channel in the apical membrane of an epithelial sheet with the five cardinal characteristics described above allowed transepithelial transport of sodium, and later Curran defined how such vectorial transport of sodium could be coupled to the iso-osmotic vectorial transepithelial flow of water and other solutes. To allow these mechanisms to create a net flux, anion had to be allowed to passively accompany the transported Na^+ since macroscopic electroneutrality had to be maintained on both sides of the epithelium, as it required an enormous amount of energy to separate charge across a membrane. As will be discussed below, if there is no pathway for chloride movement, as occurs in cystic fibrosis, transepithelial salt and water flow are greatly impeded.

8.3 Ion Channel Dysfunction and Diseases in Epithelia

On one hand, the macroscopic phenotypes produced by defects in epithelial channels can be seen to reflect the wide range of specific uses to which Nature has put epithelia: failure of lung, kidney, digestive and other internal organs, deafness, systemic fluid and electrolyte abnormalities, and even abnormalities of morphogenesis. On the other hand, these phenotypes all ultimately can be recognized to arise from defects in either of the two cardinal functions of epithelia, transepithelial transport, or maintenance of transepithelial gradients.

8.4 Cystic Fibrosis

Cystic fibrosis is the most common simple genetic disease in Caucasians, nearly 5% of the members of those populations carrying one pathogenic allele for this lethal autosomal recessive disease, with one common allele, Δ F508, reflecting 70%, but at least four other pathogenic alleles also reaching polymorphic gene frequencies (~1%) and over 1000 alleles now being known. It is also the first genetic disease for which the etiological gene and pathogenic alleles were discovered strictly

on the basis of only its chromosomal position, without benefit of a known protein or a pathogenic allele created by a chromosomal rearrangement. It was additionally a landmark since it represented the first genetic channelopathy. The clinical phenotype of this disease – predominated by failure of lung, pancreas, and intestinal function – suggests nothing to bring to mind ion channel processes in the context discussed for the excitable tissues, and only slowly is the full molecular pathophysiology of this disease coming to light.

The gene, *CFTR*, standing for ''cystic fibrosis transmembrane regulator,'' encodes a large transmembrane protein with 12 transmembrane helical spans, two cytosolic ATP-binding domains, and a large cytoplasmic regulatory domain that has multiple phosphorylation sites (Fig. 5). It is itself an ATP-regulated chloride channel, activated by the combination of both direct ATP binding and ATP-dependent phosphorylation via a cAMP-dependent kinase.

How does loss of function of this epithelial chloride channel produce the multifaceted phenotype of CF? The key features of the disease reflect epithelial dysfunction and include very thick dehydrated mucus secretions in the respiratory tree, which become purulent with chronic infections and progress to destruction of the lung parenchyma and therefore chronic respiratory failure. Additionally, a majority of patients have malabsorption caused by pancreatic insufficiency, caused by plugging of the secretory ducts resulting in activation of the digestive enzymes within the ducts and eventually pancreatic fibrosis (hence CF's old names ''mucoviscidosis'' and ''cystic fibrosis of the pancreas''). As medical treatment allowed a longer lifespan, it was recognized that nearly all males at adulthood have infertility caused by plugged atretic vasa deferens and that a few percent of the patients first presented as newborns with meconium ileus, an obstruction of the newborn's intestines caused by cement-like intestinal contents. The physiology of these complex secretory processes was insufficiently understood to lead to an understanding of this disease or its diagnosis. However, the modern scientific underpinnings of CF began during a New York heat wave in 1953, when it was astutely observed that many of the children who were hospitalized for dehydration and salt depletion came to be diagnosed with CF. The dehydration arose because they secreted a salt-rich sweat. This observation led di Sant'Agnese and coworkers to the development of the diagnostic ''sweat chloride test'' based upon the recognition that the high concentration of chloride in sweat of CF homozygotes, well before they became symptomatic, could be distinguished from unaffected controls or carriers. Not until 30 years later did patch-clamp electrophysiology studies on the sweat gland by Quinton and coworkers establish that a defect in the function of an epithelial chloride channel prevented the physiological resorption of salt from sweat during its transit through the duct. Therefore, the cardinal aspects of transepithelial transport, salt and water movements, were impeded by the CF chloride channel defect. As the sweat gland was a *resorptive epithelium*, salt resorption was prevented, so salt was wasted in sweat. The same molecular lesion in the *secretory epithelium* of the respiratory mucus gland, the pancreatic acinus, and the vas deferens resulted in concretions of dehydrated product that plugged and scarred the ducts, ultimately destroying the tissues.

Despite the complicated name of the CFTR channel it is clear that this protein *itself* functions as an ion channel, not just an indirect regulator of other channels. This

point is most simply made by classes of mutant alleles that alter ion selectivity and single-channel conductance, functions intrinsic to a channel and *not* subject to its regulation. There are also informative classes that alter channel gating; however, this *is* a process subject to regulation, so such alleles do not prove intrinsic channel activity. Likewise, the vast majority of the mutant alleles are even less informative in that they merely alter the membrane protein's biosynthesis, maturation, and stability, telling little about the protein's function, but perhaps pointing to vulnerabilities that can be targeted in therapy.

8.5 Renal Channelopathies

The range of the diversity of apical sodium entry pathways available in epithelial designs is reflected in channelopathies of the kidney tubules, but mutations in the subunits of the heterotrimeric EnaC epithelial sodium channels, encoded by *SCNN1A, SCNN1B,* and *SCNN1G,* provide the simplest entry to the pathophysiology of these diseases. The α-, β-, and γ-subunits of this channel are homologous to each other and to the degenerins that participate as an olfaction and neurodegeneration channel in *Caenorhabditis elegans.* Each gene encodes a simple ion channel subunit that contains cytoplasmic termini and only two transmembrane helices (Figs. 5 and 6). Expression of the α-subunit alone produced ion channel activity *in vitro,* but it did not reflect a recognized native current. Neither the β- nor γ-subunits alone produced any channel activity. All three subunits expressed together, however, could be recognized to produce the amiloride-sensitive, aldosterone-regulated sodium channel best characterized in the principal cell of the distal nephron (Fig. 14d), but also found in the colon, lung, and exocrine glands, many places CFTR was expressed. Amiloride is a diuretic drug, and drugs we call diuretics are in fact naturetics in that they cause sodium wasting by inhibiting a renal sodium resorption mechanism. Each class of clinically useful diuretic targets a different renal epithelial apical sodium entry pathway, and, remarkably, mutations have been found targeting each of these pathways, simulating the effects of the diuretic drugs furosemide, thiazide, and amiloride.

Just as without a rudimentary understanding of transepithelial transport one would be unlikely to guess the phenotype of CFTR mutations, it takes at least a superficial appreciation of renal physiology to derive the phenotype produced by these mutations: alterations in blood pressure. These days we tend to forget that salt is a precious essential ingredient for life and that loss of body salt (much more than loss of body water, as will be discussed below) results in blood volume depletion and a syndrome of shock similar to that produced by a severe hemorrhage. While the sweat gland is a relatively simple structure that does a fair job of resorbing some salt from the small volume of blood ultrafiltrate that gives rise to the excreted fluid, the kidneys are Olympic performers in this field in that they cope with fully one-fifth of the cardiac output, sending one-fifth of that across the glomerular filter (G) into the epithelial nephron tubules, where in excess of 99.5% of the salt can be reabsorbed by crossing the luminal apical membrane and then the basolateral membrane back into the blood, leaving by default unspecified waste to be lost in the urine (Fig. 14). The epithelial sheet that forms the nephron tubule changes in character along its length, and classical renal tubule

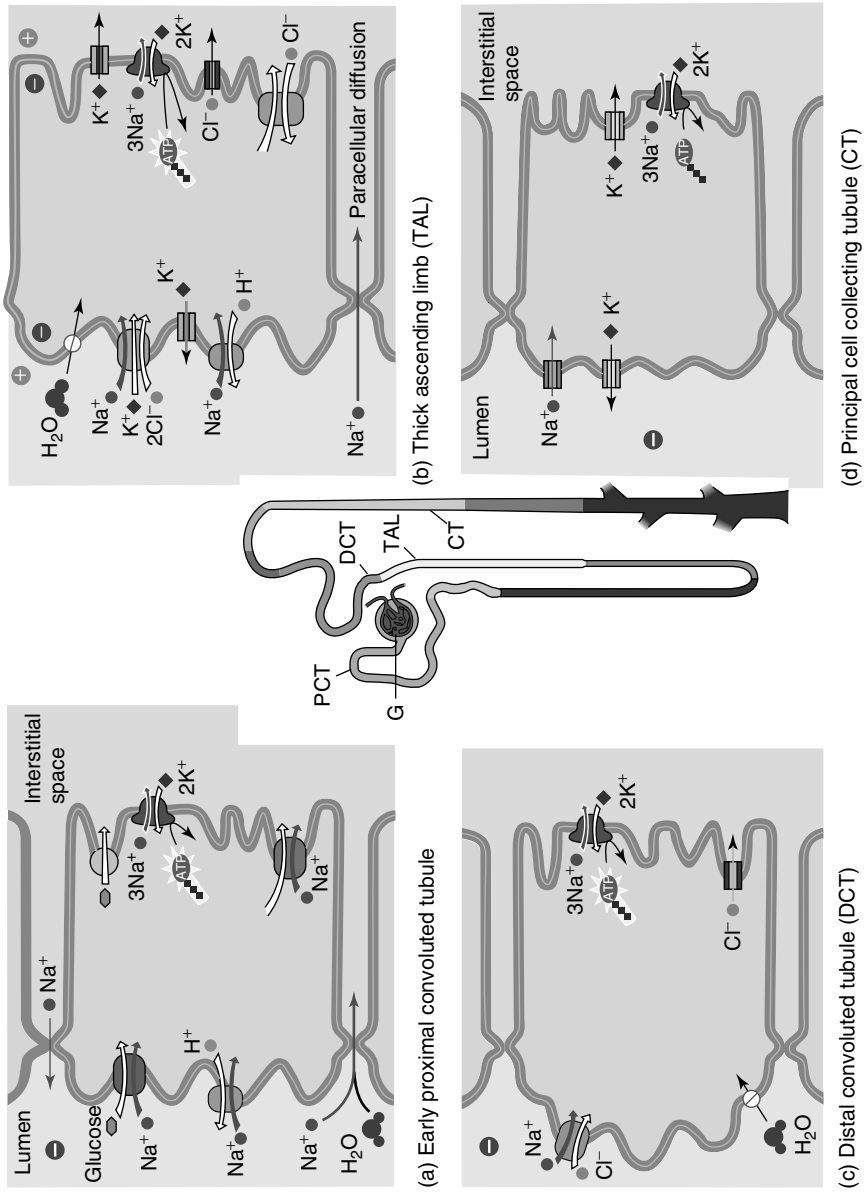

Fig. 14 Renal epithelia.

segment names have now come to be associated with specific molecular transport mechanisms. For instance, 66% of the filtered salt is resorbed in first segment, the proximal tubule (PCT), 25% in the thick ascending limb (TAL) of the loop of Henle via the furosemide-sensitive apical Na-K-Cl cotransporter, 7% in the distal convoluted tubule (DCT) via the thiazide-sensitive apical Na-Cl cotransporter, and the final 2% via the amiloride-sensitive, aldosterone-regulated heterotrimeric EnaC epithelial sodium channels in the collecting tubule (CT) (Fig. 14).

The kidney is capable of regulating sodium resorption over a wide range to compensate for changes in intake, using only the final 2% of the filtered load. This is all achieved by control of the abundance of the EnaC epithelial sodium channels in the principal cells of the CT by the adrenal steroid hormone aldosterone (Fig. 14d). Aldosterone is secreted in response to angiotensin II, which in turn is produced from angiotensin I by angiotensin converting enzyme (ACE), an important pharmacological target for the control of blood pressure. The entire cascade leading to aldosterone is initiated in response to sensors that detect aspects of blood volume, critical ones being the intrarenal and central baroreceptors that trigger specialized cells in the nephron to release an enzyme, called *renin*, which cleaves the inactive angiotensinogen precursor to angiotensin I. Therefore, hemorrhage causes a low blood volume and pressure to be sensed, triggering renin release, leading to the production of angiotensin and aldosterone, the insertion of excess EnaC epithelial sodium channels in the principal cells of the CT, enhanced distal nephron sodium resorption into the blood and a physiological trend to restoring blood volume. On the other hand, artificially producing high blood pressure will homeostatically decrease renin release, leaving angiotensin and aldosterone levels low, reducing the abundance of EnaC epithelial sodium channels and distal nephron sodium resorption, wasting sodium in urine and diminishing blood volume. Because the transepithelial electrical potential across the ''tight'' CT epithelium is used to drive the secretion of potassium and hydrogen into the nephron lumen, and that electrical potential results from EnaC sodium channel activation, a low abundance of EnaC sodium channels results in reduced K^+ and H^+ wasting in the urine, and hence elevated plasma levels of both. Conversely, high levels of EnaC sodium channels enhance K^+ and H^+ wasting and low plasma levels of both.

8.6 Pseudohypoaldosteronism and Liddle Syndrome

Loss-of-function mutations, primarily produced by deletions, in *SCNN1A*, *SCNN1B*, and *SCNN1G* genes, encoding subunits of the EnaC channel, produce the phenotype of autosomal recessive pseudohypoaldosteronism type 1. This is a severe disease that presents in infancy with life-threatening failure to thrive caused by salt wasting and hypovolemia. They additionally have hyperkalemia and metabolic acidosis. As the name implies, the phenotype appears like that produced by an absence of aldosterone; however, in this case aldosterone (as well as angiotensin and renin) levels are very high. One allele, *SCNN1B G37S*, replaces a conserved glycine residue of the channel with serine, thereby altering gating and reducing the channel open probability. This establishes that channel function *itself* is critical to the phenotype, not some other aspect of

the protein. This phenotype powerfully defines the physiology: all of the complex and apparently multifaceted actions of aldosterone can be understood to emanate from increasing the EnaC channel current, since loss of the hormone and loss of the channel appear indistinguishable. The sodium current conducted by the channel is the effector of aldosterone action; *a classical endocrine and hormonal pathway is truly a complex means of ion channel regulation, its diseases truly channelopathies*.

Gain-of-function dominant mutations in *SCNN1B* and *SCNN1G*, altering the C-terminus of the β- or γ-subunits of EnaC channels, cause a pseudohyperaldosterone state called *Liddle syndrome*. The phenotype is hypertension, with low renin, angiotensin and aldosterone levels, suggesting primary excess sodium retention and volume expansion. They also have hypokalemia and metabolic alkalosis, secondary to excessive renal K^+ and H^+ wasting. The mutations mainly result in increased numbers of EnaC channels in the CT; however, some alleles do increase the channel open probability, again showing the sodium current, and not some other aspect of the protein, to be critical. Since the diuretic amiloride blocks the EnaC channel, the drug is useful in treating the disease. Spironolactone, a drug that inhibits aldosterone action, however, has no effect, since the mutant channels are constitutively active and no longer under hormonal control. Not only does amiloride block the excessive sodium resorption, allowing sodium wasting, volume loss, and a normalization of blood pressure, but it also indirectly blocks excessive K^+ and H^+ wasting and corrects those plasma disorders. EnaC does *not* itself transport K^+ or H^+. Blocking the sodium channel in the CT prevents K^+ and H^+ secretion there via effects on the CT transepithelial membrane potential. For this reason, amiloride is a ''potassium-sparing'' diuretic, in contrast to all of the others to be discussed below.

8.7 Bartter and Gitelman Syndrome

Amiloride, with its ability to block EnaC channels and therefore resorption of only the final 2% of the filtered sodium load, is a relatively weak diuretic. The most potent diuretics, such as furosemide, target the apical Na-K-Cl cotransporter found in the TAL where 25% of the filtered sodium load is resorbed (Fig. 14b). The cotransporter is a solute carrier protein with 12 transmembrane helical spans encoded by *SLC12A1*. It has the ability to couple the electroneutral movement of four ions across the membrane, $1Na^+$, $1K^+$, and $2Cl^-$ (Fig. 6). The carrier's movement is passive in that no ATP energy is directly consumed in transport, but because the flows of all four ions are coupled and must take place in concert for any movement to occur, flux coupling, as was mentioned above, allows the cotransporter to capture the potential energy available in the sodium electrochemical gradient to move K^+ and Cl^- ions along with it as it enters the TAL cell across the apical membrane. This happens despite the fact that K^+ and Cl^- move uphill against their individual electrochemical gradients since it is the net electrochemical potential of the entire complex that dictates the direction of the coupled movements. This is a process called *secondary active transport*, a bioenergetic process coupled to an ion's electrochemical potential, and it is contrasted to *primary active transport*, a process coupled to the chemical potential of ATP hydrolysis and exemplified by the Na/K-ATPase, discussed above.

Loss-of-function alleles of *SLC12A1* were first recognized to cause the severe autosomal recessive disease phenotype of Bartter syndrome (BS), characterized by prenatal polyhydramnios, infantile polyuria, and polydipsia, renal Na^+, K^+, and H^+ wasting with subsequent hypokalemia and hypochloremic metabolic alkalosis, and very high renin, angiotensin, and aldosterone levels. It looked in every way as if these infants were on high doses of furosemide since conception, with the massive renal salt wasting producing the polyhydramnios, polyuria, and volume depletion that the homeostatic aldosterone signaling pathway was mightily struggling to restore. The high aldosterone was forcing a maximal EnaC channel response, but this low-capacity system could not handle the huge load of sodium the dysfunctional TAL had left behind, so sodium continued to be wasted. However, the electrical effect of maximal EnaC channel activation in the CT is present, hence the massive K^+ and H^+ wasting. Just as the EnaC channel has a major impact on the transepithelial electrical potential in the CT, and hence the flux of other ions in that renal segment, the SLC12A1 cotransporter has a major role in creating the TAL transepithelial potential, a very atypical potential in that it is lumen positive, not negative like nearly every other epithelial sheet (Fig. 14b). Physiologically, the lumen positive potential, created by the secondary active transport of Cl^- by the cotransporter, repels cations, particularly the divalent cations Ca^{++} and Mg^{++}, favoring their paracellular resorption and being the major site in the nephron at which they are resorbed. With the loss of SLC12A1 function, the divalent cations are wasted in the urine and the blood levels fall.

Since the SLC12A1 cotransporter carries an electroneutral load of two cations and two anions, it appears puzzling it should be able to create the unusual lumen positive condition. This arises because of two types of critical ion channels in the TAL apical and basolateral membranes (Fig. 14b). Mutations in these channels also produce the BS phenotype, BS type 1 used to specifically designate the disease caused by *SLC12A1* mutations. Since the TAL cells have a high internal K^+, the energetics of cotransport are favored by allowing K^+ to futilely recycle back into the lumen across the apical membrane. This apical potassium channel, the ATP-sensitive ROMK channel encoded by *KCNJ1*, a member of the channel family causing Andersen syndrome (Figs. 5 and 8), was shown to be essential to TAL transepithelial transport since loss-of-function mutations in this gene produced the Bartter syndrome phenotype, BS type 2. The high abundance of ROMK channels in the apical membrane of the TAL contributed half of the explanation for the unusual positive transepithelial potential; abundant K^+ channels gave the apical membrane a hyperpolarized membrane potential nearer the K^+ Nernst potential (Fig. 14b). The last part of the puzzle is the presence of abundant Cl^- channels in the basolateral membrane (Fig. 14b). They depolarize the basolateral membrane potential, and therefore accentuate the difference in potential between the two faces of the TAL cell. They are there to provide a pathway for Cl^- to leave the cell and passively reenter the blood, accompanying Na^+ and effecting net salt resorption in the TAL – the classical ''diluting segment'' of the tubule where hypotonic luminal fluid is produced. The basolateral Cl^- channel is composed of subunits from the large CLC channel family (Fig. 5) that includes the muscle chloride channel underlying Becker and Thomsen myotonia, discussed

above. A crystal structure has recently been obtained for this family of chloride channels, showing them to function as ''double-barreled'' dimers with each subunit, composed of 18 helical segments and both termini on the cytoplasmic face, having its own ion conduction pathway. The specific subunits found in the kidney are encoded by *CLCNKB* and *CLCNKA*, which are inserted in the membrane accompanied by barttin, their small β-subunit having two transmembrane helices and encoded by *BSND*. Recessive loss-of-function mutations in *CLCNKB* cause classical Bartter syndrome, BS type 3. Bartter syndrome, type 4 is caused by homozygosity for loss-of-function alleles of *BSND*, but this phenotype additionally includes sensorineural deafness. This same set of phenotypes is produced as a *digenic* syndrome with loss-of-function alleles of *both CLCNKB* and *CLCNKA*.

Channelopathies as a cause of deafness were briefly mentioned in the context of recessive cardiac LQT syndromes in Sect. 5.6. Surprisingly, the same channel is expressed selectively in the heart and the inner ear epithelium, where its abundant expression is involved in the production of the potassium-rich endolymph fluid that fills this chamber and participates in the transduction of auditory sensation. Only complete loss of the channel significantly disturbs this secretory process. It is of note that another inner ear *LQT1* homolog, encoded by *KCNQ4*, has dominant alleles that produce only deafness without LQT (*DFNA2*). Just as even a small amount of LQT channel function, such as provided by the dominant LQT alleles, was sufficient for production of the KCl-rich fluid of the inner ear compartment – deafness only occurring with a profound homozygous loss of function – only complete loss of inner ear epithelium chloride channel function causes deafness. The chloride that accompanies potassium in endolymph production passes through the *CLCNKB*- and *CLCNKA*-encoded channel. Without barttin, neither the *CLCNKB*- nor *CLCNKA*-encoded channel can be inserted into either the TAL or inner ear epithelial basolateral membrane. Either channel alone is sufficient to maintain the endolymph production for hearing, but only the *CLCNKB*-encoded channel can support the higher demands of TAL function.

Gitelman syndrome is the result of homozygosity for loss-of-function mutations in *SLC12A3*. It encodes a close relative of the Na-K-Cl cotransporter, called the *thiazide-sensitive Na-Cl cotransporter* to reflect its sensitivity to the thiazide class of diuretics and the K^+ insensitivity of the transport mechanism (Figs. 6 and 14c). This apical cotransporter is found in the DCT of the nephron and is responsible for the resorption of 7% of the filtered sodium load (Fig. 14c). Like Bartter syndrome, the disease presents with renal Na^+ wasting and a secondary wasting of K^+ and H^+ as well as resultant hypokalemia and hypochloremic metabolic alkalosis, as aldosterone and the EnaC channels struggle to correct the volume loss, which ultimately is only minor. Renin, angiotensin, and aldosterone are all elevated; however, the disease is much milder than Bartter syndrome, since the DCT resorbs a much smaller fraction of filtered sodium. Therefore, it classically presents in adolescence, but the presenting picture is *not* one of volume depletion, it is rather a picture predominated by consequences of the chronic plasma electrolyte abnormalities and their impact on excitable tissues. This is commonly manifested as muscle weakness, abdominal pain, and neuromuscular irritability. Patients commonly have hypomagnesemia and accompanying tetany,

although the pathogenesis of this abnormality remains to be elucidated.

It should be noted that one would expect hypomorphic alleles in the five genes contributing to Bartter and Gitelman syndrome and the three genes contributing to the EnaC channel to be protective against hypertension. Conversely, hypermorphic alleles in these same eight genes have the potential to contribute to hypertension. Therefore, polymorphic variants of these genes are promising candidates for evaluation in the heritable polygenic trait of blood pressure.

8.8 Hypomagnesemia

Autosomal recessive primary hypomagnesemia has played an important role in beginning to reveal the mechanisms underlying the paracellular pathways of epithelial ion transport, revealing them to be far more complex than simply an unmediated leak between cells (Fig. 14b). The disease presents in early childhood with symptoms similar to Gitelman syndrome, but additionally polyuria and renal stones. It is caused by homozygosity for loss-of-function alleles of *CLDN16*. This gene encodes Paracellin-1, a transmembrane protein with four helical spans found in the TAL and DCT tight junctions where it appears to contribute to a calcium and magnesium selective paracellular path. This gene family appears to encode proteins designated for such paracellular epithelial transport pathways since *CLDN4* and *CLDN15* also influence ion selectivity in other tight junctions.

Autosomal dominant hypomagnesemia appears to arise by a very different mechanism. It was shown in a large extended family to cosegregate with a heterozygous missense mutation in *FYXD2*, the gene encoding the small single membrane-spanning proteolipid γ-subunit of the Na/K-ATPase, a modulatory subunit found associated with the functional $\alpha\beta$ subunits only when the pump is expressed in basolateral membranes of the distal nephron. This subunit alters the transport kinetics of the ion pump, the prime mover setting the gradients and energetics for all coupled transport in these tight epithelia. The pathological *FYXD2 G41R* allele must function as a dominant negative gain-of-function allele, since haploinsufficiency produced by heterozygous deletions spanning the locus does not produce the phenotype. The mutation alters charge in the middle of the transmembrane helix and causes the γ-subunit to fail to traffic beyond the golgi, allowing functional $\alpha\beta$ subunit insertion into the membrane alone. As this is the only pathogenic allele reported to date, the mechanism by which mutations in this locus produce magnesium wasting remains unclear.

Hypomagnesemia with secondary hypocalcemia is caused by homozygosity for loss-of-function mutations in the *TRPM6* gene, over a dozen pathogenic alleles already known. This gene, and other members of its large extended family, are cousins of the genes encoding the pore-containing hexahelical channel subunits of voltage-gated K^+ channels, described in Sect. 3; however, the TRP branch of the family encode an array of selective and nonselective tetrameric cation channels that are coming to be recognized as playing important roles in sensory transduction and epithelial function (Fig. 5). The TRPM6 and TRPM7 channel subunits, each of which contains a C-terminal protein kinase domain, appear to heteromultimerize to form a Mg^{++} channel and pathogenic alleles of *TRPM6* prevent

subunit association and channel function. No pathogenic alleles, however, have yet been reported in *TRPM7*.

8.9 Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is one of the most common genetic conditions, affecting over 1/800 births and responsible for 10% of chronic dialysis. Mutations – primarily null alleles caused by deletions, nonsense, frameshifts or splicesite alterations – in a relative of the TRP family of genes, PKD2 – encoding polycystin-2 – and in PKD1 – encoding polycystin-1, its homologous heteromultimerizing partner – cause this disease, and produce cystic dilation of kidney tubules, hepatic cysts, and aneurysms in blood vessels. Most of the nephrons appear normal, suggesting a ''two-hit'' pathogenic model reflecting a germline loss-of-function mutation and probabilistic somatic loss-of-heterozygosity (LOH), similar to that which has proved so powerful in understanding dominant cancers. Coexpression of PKD1 and PKD2 *in vitro* produce functional calcium-permeable nonselective cation channels, but expression of either PKD1 or PKD2 alone does not, and pathogenic alleles prevent heteromultimerization and channel function. The channels are found localized in association with the cilium, a structure of the apical membrane, perhaps transducing mechanical sensory signals it detects. While it is clear that calcium signaling is induced by the cilium and perturbed by the mutant alleles, it is unclear how either alters morphogenesis producing cyst formation. However, recently a clear example of morphogenetic pattern formation, left-right axis asymmetry, was shown to require epithelial PKD2 function.

8.10 Glucosuria

The notion that energy conserved in the sodium gradient across the apical membrane of an epithelial cell can be used in secondary active transport was introduced above in discussing Bartter and Gitelman syndrome. Sodium-coupled transport, however, is used in the gut and nephron in the resorption of many uncharged metabolites, not only ions (Fig. 6). A clear picture of how such energy coupling occurs is provided by two autosomal recessive glucose-wasting disorders. The sodium gradient across the apical membrane arises as a consequence of Na/K pump activity at the basolateral membrane. Secondary active transport of a substance, in this case glucose, occurs ''uphill,'' against its electrochemical gradient by being obligatorily coupled on a carrier protein to the movement of sodium down its electrochemical gradient into the cell, such that the net movement of the coupled system obeys thermodynamics and remains ''downhill'' (Fig. 14a). A tremendous amount of energy is stored in the sodium gradient. A simple estimation reveals that cellular sodium is about 1/10th that found in the renal tubular fluid and that the membrane potential is ~ -60 mV – the Nernst equation revealing that translates to the equilibrium diffusion potential set up by a 10-fold gradient of a monovalent ion (*see* Sect. 2). Both the 10-fold chemical gradient and the equivalent 10-fold electrical gradient favor movement of Na^+ into the cell, and those potentials are multiplicative. This should allow 1 : 1 coupling of sodium:glucose to drive cellular glucose to a concentration 100 times

that found in tubular fluid. Should one obligatorily couple the movement of two sodium ions to cotransport with one glucose, the multiplicative properties suggest one could achieve the 100-fold enhancement for *each* Na^+ site, and hence a 10 000-fold gradient favoring glucose absorption. These are the properties of SLC5A2, the low affinity 1 : 1 apical sodium-glucose cotransporter and SLC5A1, the high affinity 2 : 1 apical sodium-glucose cotransporter, respectively.

Isolated renal glucosuria is caused by homozygous loss-of-function mutations in *SLC5A2*. The high-capacity, low-affinity cotransporter it encodes is glucose-selective and is abundantly expressed in the apical membrane of the initial segment of the proximal tubule of the kidney, the site where the majority of the glucose filtered across the glomerulus is reabsorbed (Fig. 14a). Physiologically, no glucose remains in the urine unless blood levels become so high that they overwhelm the transport capacity of this transporter, as occurs in diabetes mellitus. Therefore, the symptoms of this transport defect are massive glucosuria, and the resultant diuresis of water obligated by this large osmotic load.

Homozygous loss-of-function alleles of *SLC5A1* cause a severe neonatal dehydration syndrome; however, this is because of diarrhea, not the renal loss it produces. The disease caused by these mutations is glucose-galactose malabsorption, and it is characterized by loss of high affinity glucose transport in the kidney and gut. This high-affinity cotransporter is expressed in the apical membrane of the final segment of the proximal tubule where it scavenges the last of the glucose missed by the SLC5A2 cotransporter. Its low capacity, however, is easily overwhelmed, so it cannot compensate for loss of *SLC5A2*. Unlike SLC5A2, it transports galactose in addition to glucose, and is the mechanism that predominates intestinal absorption of these sugars – essential for a newborn dependent on the lactose of milk. Just as sugar left behind in the lumen of the nephron osmotically obligates water loss, so too does this unresorbed intestinal sugar; however, providing the infant a formula of fructose, a sugar that uses a different transporter, is life-saving.

8.11 Nephrogenic Diabetes Insipidus

Ancient physicians recognized that not only could diabetes, characterized by excessive urination and thirst – polyuria and polydipsia – be accompanied by sugary-sweet tasting urine – diabetes mellitus – but could alternatively be accompanied by tasteless urine – diabetes insipidus. Autosomal nephrogenic diabetes insipidus (NDI) results from defects in water channels, called *aquaporins*, and a recent Nobel Prize was awarded for the solution of their nature. Aquaporins reflect a large family of water channels and their function – allowing the flow of water while excluding that of ions, is the mirror image of that of ion channels, which allow the flow of ions without water. Loss-of-function recessive and dominant-negative alleles of *AQP2* result in NDI and in a loss of regulated water channels from the apical membrane of the principal cell of the CT (Fig. 14d), the site of regulated water resorption in the kidney. The peptide hormone alternatively called *vasopressin* or antidiuretic hormone (ADH), and long known to be responsible for the production of concentrated urine is tonically secreted by the pituitary in response to small changes in plasma osmolarity. It was shown to control insertion of the

AQP2 channel into the apical membrane of the principal cell; in the absence of hormone, the aquaporin was sequestered in vesicles beneath the membrane and hormone receptor signaling through cAMP triggered insertion of the channels. The receptor receiving the ADH signal, called the *V2 vasopressin receptor*, is encoded by the X-linked gene *AVPR2* and mutations in this gene were shown to cause the X-linked, more common form of nephrogenic diabetes insipidus. The phenotype in NDI, lethargy progressing to coma, results from effects on excitable tissues of euvolumic hypernatremic hyperosmolarity, as water is wasted by the kidney in excess of salt. Note that both major hormones involved in salt and water balance act independently by directing the insertion of different apical channels into the principal cell of the CT: aldosterone regulates sodium balance and hence plasma volume via the insertion of epithelial sodium channels and ADH regulates water balance and hence plasma osmolarity via the insertion of aquaporin-2.

8.12 Hereditary Kidney Stone

Kidney stone formation, nephrolithiasis, is a common polygenic trait with a lifetime risk of up to 10%. Stones are crystal-like structures that precipitate from urine within the kidney. Their origin is now recognized to be an abnormal urine environment, and recently defects in renal ion channels have been shown to contribute to this phenotype. Above it was briefly mentioned that stone formation was a component of the phenotype in primary hypomagnesemia. Nephrolithiasis is most commonly associated with hypercalciuria and calcium salts are a key component of most stones. Loss-of-function alleles of *CLCN5*, encoding a voltage-gated chloride channel within the family of those causing Bartter syndrome and myotonia (Fig. 5), described above, were recognized to cause a Mendelian X-linked form of hypercalciuria and stone formation, called *Dent disease*, a phenotype that additionally included proteinuria and progressed to renal failure. Additional alleles in the same gene were found to cause two other diseases that had not previously been recognized to be related, X-linked nephrolithiasis and X-linked hypophosphatemic rickets – a phenotype characterized by demineralization of bone. This chloride channel is localized to endosomes within epithelial cells of the proximal tubule, *demonstrating that ion channels play a critical part not only in the function of cellular membranes but also of subcellular compartments*. Defects in the function of the endosomal Cl^- channel impair the process of endocytosis from the apical membrane, secondarily altering the regulation of various apical transporters, but the exact mechanism of pathogenesis remains to be defined. It is of note that homozygous loss-of-function and heterozygous dominant-negative mutations in its close relative *CLCN7*, while causing a distinctly different phenotype, osteopetrosis, ultimately produce the phenotype as a result of a failure in endosomal function. Further, homozygous loss-of-function alleles in *TCIRG1*, encoding a subunit of the endosomal vacuolar ATPase proton pump (Fig. 6), also produce osteopetrosis. Osteopetrosis is a phenotype that includes very dense bone since bone remodeling by the degradative bone osteoclasts fails because endosomes fail to function since they can not acidify. Together, the two osteopetrosis diseases loci suggest that the endosomal Cl^- channels provide a shunt pathway that allows the endosomal H^+-ATPase to pump a proton gradient without stalling because

of electrostatic charge accumulation, and suggest a similar role for *CLCN5* in the kidney.

9 Ion Channel Disease of Other Nonexcitable Tissue

In addition to major phenotypes produced by defects directly assignable to abnormalities in the function of heart, muscle, nerve, and epithelia, ion channel defects are already known to produce a wide array of ancillary phenotypes, some of which were mentioned above as additional components to a syndrome, for instance, the skin findings produced by alleles producing deafness in the three gap junction loci, mentioned at the end of Sect. 7.7. Further, new channel phenotypes are coming to be recognized as arising from a failure of internal membranous organelle function, and these organelles play similar functions in most cell types. In these other tissues, channels seem to play pathophysiological roles similar to those played in diseases of excitable tissues or epithelia. For instance, the mirror-image pancreatic β-cell endocrine channelopathies of hyperinsulinism in infancy (HI) and permanent neonatal diabetes (PND) are very similar to neuronal receptor/channel disease, once the special mechanism of glucose sensing by the ATP-sensitive sulfonylurea receptor/channel is taken into account. This receptor/channel contains K^+ channel subunits, encoded by *KCNJ11* (from the family of those involved in Andersen and Bartter syndromes, discussed above) (Figs. 5 and 8), and a regulatory ATP-binding cassette subunit, encoded by *ABCC8*, named *SUR* for the sulfonylurea (SU) drugs that interact with it. Blocking this K^+ channel depolarizes the membrane, activating voltage-activated Ca^{++} channels and a calcium influx that triggers excitation-secretion coupling (as described in Sect. 7.1) with the fusion of insulin-laden vesicles into the β-cell membrane, and hence insulin secretion into the blood. Glucose induces insulin release through its metabolism in the β-cell, the ATP produced serving to block the channel; the SU drugs induce insulin release by directly blocking the channel's conductance. Not surprisingly, HI, which simulates the effect of SU, is caused by homozygosity for loss-of-function mutations in either of the two channel subunits. PND, where insulin can not be released, results from heterozygous dominant gain-of-function missense alleles of *KCNJ11*, which produce constitutively active channels that cannot respond to physiological ATP block induced by glucose, but can respond with insulin secretion when blocked by an SU. Notice how these alleles and the mirror-image phenotypes they produce are reminiscent of the mirror-image "endocrine" EnaC renal channelopathies, discussed in Sect. 8.6. As a second example, osteopetrosis, a defect in bone morphogenesis caused by defects in Cl^- channels and ultimately endosomal function, was briefly mentioned above as an endosomal channelopathy, an initial case of a disease caused by defects in membrane compartments *within* cells. Other membrane compartment channelopathies are beginning to emerge: endoplasmic reticulum channelopathies and MHS, caused by alleles of *RYR1*, discussed above in Sect. 6.4; lysosomal channelopathies and the lysosomal storage disease mucolipidosis type IV, caused by loss-of-function alleles in *MLN1*, encoding a lysosomal TRP-like nonselective cation channel; and mitochondrial channelopathies and severe obesity with diabetes, caused by

loss-of-function alleles of *UCP3*, encoding a mitochondrial proton channel that shuts protons across the membrane and thereby uncouples respiration from ATP synthesis, physiologically making mitochondria less efficient, and the disease appearing to result from hyper-efficient mitochondria.

10 Ion Channels as Targets for Drug Therapy in Common Diseases

For the discovery of a pathogenic allele to have full impact in modern medicine, it is necessary to understand its function and to find small molecules able to alter that function – such ''rationally designed'' novel pharmaceuticals being one of the major hopes for the postgenomic era. While often positionally identified disease genes have been slow to yield either their function or a ''rational drug,'' ion channels are highly amenable and proven targets. For example, discovering ion channel participants in a disease, such as the Mendelian seizure disorder caused by alleles of *KCNQ2* and *KCNQ3*, suggests not only a novel *type* of target for therapy (e.g. suggesting use of acetazolamide – a drug proven effective in a wide range of ion channel diseases), but these channels themselves can further serve as the guides to *finding* entirely novel selective pharmaceuticals. Because the function of channel mechanisms is so well understood, and it is now clear that the *full* range of pathogenic abnormalities in the huge ensemble of channel diseases discussed above is either too much or too little conductance through the channel (not *anything* else), one does not need to guess what has to be changed to remedy the gene defect. It is clear that the therapeutic goal must be to discover a channel closer/blocker or a channel opener/activator, and a number of drugs of both types are already in current use. *In vitro* expression assays of channel function can be used in high-throughput drug screening and in drug optimization. An example of this kind of breakthrough is retigabine, a novel class of seizure medication proven to activate the KCNQ2/KCNQ3 ''M current'' channel suggested as a seizure drug target by the role of these genes in BFNC. Since the channel mechanisms perturbed in such disorders are likely to be critical participants in producing the relevant membrane potentials leading to disease vulnerability, the drugs targeting them should be useful for treating the disease even in those *not* having an intrinsic defect in the targeted mechanism (i.e. even if a patient has the disease because of a pathologically depolarized critical membrane because of some *other* mechanism, hyperpolarizing the implicated membrane via *any* mechanism should be helpful). Another advantage of pharmacology targeted to channels is the expectation, discussed above, that *a narrow range of tissues express the channel in a physiologically important context, therefore drug specificity is achieved and unwanted side effects are minimized*. Therefore, in this postgenomic world rich in potential therapeutic targets, the potential channels hold for rapid novel drug discovery warrants their prioritization.

Most of the diseases discussed in this chapter are rare channelopathies and despite being promising targets for pharmacological intervention would likely remain ''orphan'' diseases were it not for the fact that they produce a *phenocopy* of a common disease, and perhaps provide the only molecular lead to a new drug urgently needed by a major market. However, it is likely that many of the loci critical to the development of the

common complex polygenic diseases *cannot* be revealed by major-effect Mendelian alleles, such alleles perhaps being early embryonic lethals. An increasingly important approach to the identification of genes underlying complex polygenic disease is to identify ''functional candidates'' within broad chromosomal regions implicated in the disease and to test disease association (i.e. linkage disequilibrium) with polymorphic markers within these candidates. Ion channel candidates in such diseases could be suggested by the known physiology, pharmacology and pathophysiology, their appropriate or extremely narrow tissue distribution, their membership in a demonstrably pathogenic gene family, contribution to a demonstrably vulnerable component of the action potential, or a salient disease-associated motif. The existence of alleles sharing features common to known pathogenic alleles underlying the monogenic channelopathies, such as dominant-negative inhibition of expressed channel function or incomplete inactivation, would be particularly suggestive.

Keywords

Crossing-over
A recombination that involves physical exchange of DNA between nonsister strands of homologous chromosomes, resulting in a nonparental combination of linked markers.

Gene Conversion
Nonreciprocal recombination between homologous chromosomes with one allele being the donor of information to convert the recipient allele to the donor sequence.

Heteroduplex
DNA hybrid formed from single strands of two nonsister chromatids; an intermediate in recombination.

Holliday Junction
Crossed-strand structure consisting of two DNA duplexes joined by a bridge as an intermediate in recombination.

Mismatch Repair
Repair of mismatched bases in heteroduplex DNA by a mismatch repair system, resulting in homoduplex DNA.

Nonhomologous End Joining
Joining of blunt ends or ends with microhomologies of usually 2 to 4 bases.

Resolution
Cutting of the Holliday junction by a resolvase to disconnect the recombining DNA duplexes and restoring the parental configuration of markers or resulting in a nonparental configuration of markers termed crossovers.

Strand Exchange
One of the processes to form heteroduplex DNA during recombination in which a strand from a homoduplex is displaced and a strand from a nonsister duplex is transferred to form a hybrid region on the chromatid.

Transformation
Addition of exogenous DNA to a cell to change the genotype of the recipient cell.

Homologous recombination (HR) is an essential activity of all cells as it is one of two major pathways used to repair potentially lethal double-strand breaks (DSBs). DSBs arise from many sources. They may be induced by exogenous agents such as ionizing radiation or chemicals that modify the DNA bases of the DNA backbone, such as methylmethane sulfonate, bleomycin, or mitomycin C. Agents that inhibit DNA topoisomerases, such as cisplatin, also cause DSBs. Endogenous DSBs may occur from programmed breaks, such as those involved in immune system V(D)J recombination of vertebrates, faulty topoisomerases, or oxygen free radicals. When the DNA replication apparatus encounters bulky lesions or a nicked template strand, DSBs may form, collapsing the replication fork. Alternatively, the replication fork may stall with single-strand DNA at the fork. This is a substrate for HR, or further processing to form a DSB. These DSBs are repaired by HR or nonhomologous DSB rejoining events. Therefore, although mitotic HR occurs at significantly reduced rates compared to meiotic HR, it is nonetheless an essential aspect of vegetative growth.

HR is essential for maintaining integrity of the genome, for preventing chromosome rearrangements, for preventing changes in chromosome number, for telomere maintenance when the normal telomere replication pathway is defective, and for preventing the occurrence of alternate double-strand break repair pathways that may result in loss of heterozygosity (LOH) events. Since spontaneous DSBs occur in every replication cycle in vertebrate cells, HR is an essential function of a normal replication cycle. Meiotic HR may also be linked to repairing premeiotic DNA replication errors, but its main purpose lies in ensuring genetic variation and proper chromosome segregation. Meiotic HR gives genetic variation to future generations by providing new combinations of alleles in the gametes. The most important function of meiotic HR is to provide a mechanism for proper segregation of homologous chromosomes at the first meiotic division. In the absence of crossing-over, chromosomes do not disjoin at the first meiotic division and give rise to aneuploid meiotic products. In this chapter, the current models for double-strand break repair by HR are reviewed, differences between mitotic and meiotic HR are discussed, and the consequences of defective HR are considered.

1 Homologous Recombination Events

1.1 Homologous Recombination (HR) Mechanisms

Homologous recombination (HR) uses information from a homologous DNA sequence, usually the sister chromatid or the homolog chromosome, to accurately repair a double-strand break (DSB), and in the process HR can transfer information from the donating DNA duplex to the recipient DNA duplex. Traditionally, HR has been thought of as reciprocal exchange of nonsister chromatids. Crossing-over, often referred to as *reciprocal recombination*, involves the physical joining of two parental molecules of homologous chromosomes. Genetically this is detected as recombinant progeny. If one parent has the linked markers AB and the other

parent has the alternate alleles, ab, the crossover products have the genotypes Ab and aB (Fig. 1a). Gene conversions, often referred to as *nonreciprocal recombination*, involve the transfer of information from one parental molecule to another parental molecule. The genotype of the donor molecule remains unchanged while the genotype of the recipient is converted to the donor genotype (Fig. 1b).

Nonreciprocal recombination or gene conversion is best studied in the fungi where all four products of a single meiosis can be recovered. Gene conversion does not result from mutation. Genetic and molecular studies have shown that the gene conversion product has the same DNA sequence as the donor sequence. Occasionally, a meiotic product is recovered that has genetic information from both parents. This mosaic product is called a *postmeiotic segregation event*. In wild-type strains, gene conversion events occur at a much higher frequency than postmeiotic segregation events. Postmeiotic segregation events result from the failure to repair a DNA mismatch in heteroduplex DNA. Mutants that are defective for mismatch repair show higher PMS frequencies and reduced gene conversion frequencies, indicating that heteroduplex formation is an intermediate in gene conversion.

1.1.1 Double-strand Break Repair

The first clues that HR is initiated by DSBs came from studies showing that

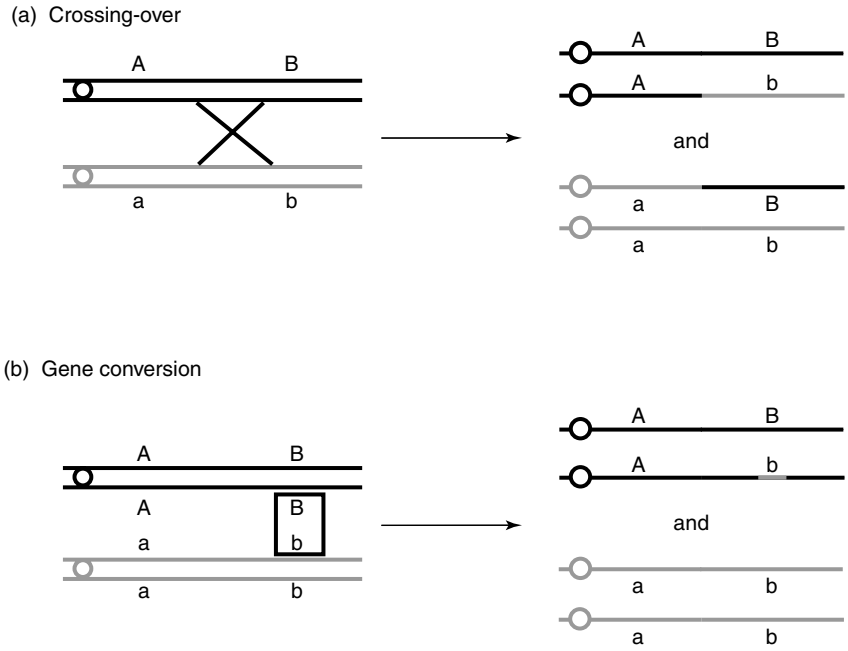

Fig. 1 Types of homologous recombination events. (a) Crossing-over, indicated by the X, generates two recombinant chromosomes and two nonrecombinant chromosomes. (b) Gene conversion, indicated by the box, yields only one recombinant chromosome. This chromosome has only a small region of substitution, at the B gene, from the donor chromosome. The donor chromosome remains unchanged, and is of the parental genotype.

HR was stimulated by ionizing radiation. This idea was further strengthened by experiments of transformation in the yeast *Saccharomyces cerevisiae*. When intact plasmid molecules that carry a yeast gene are applied to yeast cells, the cells take up the plasmid and express the yeast gene or marker located on the plasmid after it is integrated into the yeast genome. The site of integration is not random; instead, it occurs by homologous crossing-over. Thus, transformation in yeast was viewed as a model for HR. Although transformation using intact plasmid molecules is relatively efficient, the frequency could be greatly increased if the plasmid molecules were first treated with a restriction enzyme that cuts within the yeast gene located on the plasmid.

When yeast cells are treated with linear plasmid molecules, transformation still occurs by homologous crossing-over. If the plasmid molecule contains two unlinked yeast genes A and B, the plasmid molecule will integrate into either the A gene or the B gene with approximately equal efficiency in transformation experiments. However, if the plasmid is first treated with a restriction enzyme that cuts only in the A gene, then most transformation events will be integrations at the A gene, demonstrating that DSBs are highly recombinogenic.

When the linear transforming plasmid contained a gap in a yeast gene, it was repaired using the chromosomal information. This is a gene conversion event and shows that DSBs are recombinogenic for both gene conversion and crossing-over events. Transformation using gapped molecules has also been performed using molecules that contain a sequence that acts as an origin of DNA replication. As these molecules can replicate autonomously, they are not obliged to integrate, although the gap must be repaired. Transformation with such molecules was associated with repair (gene conversion) and homologous crossing-over (integration) approximately 50% of the time and with simple repair (gene conversion without crossing-over) for the remainder 50% of the time. This result gave further support for the double-strand break repair model as a general model for meiotic recombination.

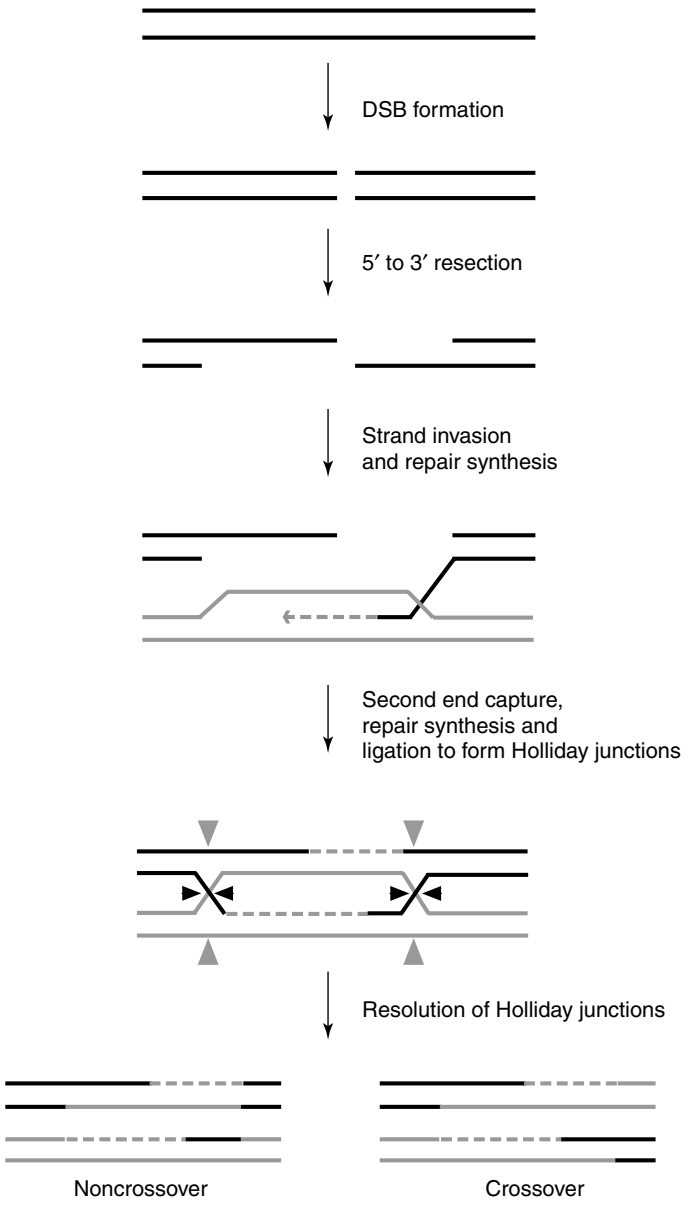
The general features of the double-strand break repair (DSBR) model for HR are shown in Fig. 2. After DSB formation, the ends of the break are resected to give 3′ single-strand tails of up to 600 nucleotides in length. The single-strand tails invade a homologous DNA sequence, and then primer synthesis from the 3′ end until synthesis fills in the gap on both strands. Ligation to the 5′ ends of the break creates a joint molecule with two Holliday Junctions (HJs). The joint molecule contains heteroduplex DNA, which is a target for the mismatch repair system. Resolution of the HJs results in crossover or non-crossover molecules. Gap repair gives rise to the gene conversion events.

1.1.2 Synthesis-dependent Strand Annealing

Although the DSBR model nicely explained why DSBs promoted HR, how a DSB could be repaired to give a gene conversion, and how crossing-over could be mechanistically linked to gene conversion via formation and resolution of the HJs, the model did not satisfactorily explain some aspects of mitotic HR. First, in other experimental systems, gap repair of a plasmid molecule was not often associated with a crossing-over event. Second, in yeast, mitotic gene conversion was not frequently associated with crossing-over. Third, mating type switching in yeast, which is DSB-promoted via the HO endonuclease,

was rarely associated with crossing-over in both haploid and diploid cells.

These observations promoted a revision of the DSBR model to form a new model that retained the features of DSB repair and gene conversion through gap filling, but did not result in intermediates with HJs. Hence, the gene conversion events were not mechanistically linked to crossing-over. The key feature of this model, called



the *synthesis-dependent strand annealing* or *SDSA* model, is a migrating D-loop that does not capture the second DSB end (Fig. 3). As in the DSBR model, the DSB is resected to give 3′ tails, one of which invades into homologous sequences on paired DNA molecule. The 3′ end primes DNA synthesis, and as synthesis proceeds, the D-loop migrates. However, the second 3′ end never is paired with the D-loop. Instead, the invading 3′ end eventually is displaced from the template duplex, and pairs with the single-strand region from the other end of the DSB. Repair synthesis fills in the gaps, resulting in DSB repair to give a gene conversion not associated with crossing-over.

SDSA has also been proposed to operate in meiosis to form all of the noncrossover gene conversion events. This will be discussed further in Sect. 3.1.

1.1.3 **Break-induced Replication**

The DSBR model is a two-ended strand invasion, where both 3′ ends of the DSB are involved in strand invasion into a homologous DNA duplex. In contrast, the SDSA model is a one-ended invasion, where only one of the two 3′ ends is involved in a strand invasion, and the other end participates in the annealing reaction. Both of these repair models are initiated from a DSB that is flanked by sequence on both sides. However, there are also DSBs that come from essentially terminal deletions, where only one side of the DBS can pair with homologous sequence (Fig. 4). Repair of this DSB by HR of necessity uses a one-ended invasion pathway. Repair is proposed to occur by processing of the DSB to give a 3′ end and invasion into homologous sequence. Repair is completed by synthesis to the end of the chromosome. This type of repair is called *break-induced replication* or *BIR*.

Evidence for BIR first came from studies in bacteria, where replication of the *Escherichia coli* chromosome was dependent on both recombination factors and replication factors. BIR differs from DSBR and SDSA in that very long tracts of DNA are replicated in a semiconservative manner. BIR was first observed in yeast from transformation with broken chromosomes. The repaired DNA fragments were linear, and contained a centromere. One chromosome arm ended in a normal telomere sequence, while the other chromosome arm was truncated internally without a telomere. This truncated arm was repaired by strand invasion into an intact homologous chromosome followed by synthesis to the end of the chromosome. This regenerated the deleted telomere and chromosome arm. The acquired sequences were identical to those from the intact chromosome arm used as template for semiconservative replication. Thus, BIR results in

Fig. 2 Double-strand break repair (DSBR) model of homologous recombination. After induction of a double-strand break (DSB), both ends are resected to yield 3′ ends. The 3′ end invades a homologous sequence and primes repair DNA synthesis using the 3′ end and the invaded strand as template. As synthesis proceeds, the second 3′ end of the DSB can be captured by either strand invasion or annealing to the displaced homologous DNA sequence. Ligation of the ends results in two-crossed strand Holliday Junctions. Resolution of the Holliday Junctions can yield noncrossover products (resolution of both Holliday Junctions by cutting at the black arrow heads) or crossover products (resolution of one Holliday Junction by cutting at the black arrow head and the second Holliday Junction by cutting at the gray arrow head).

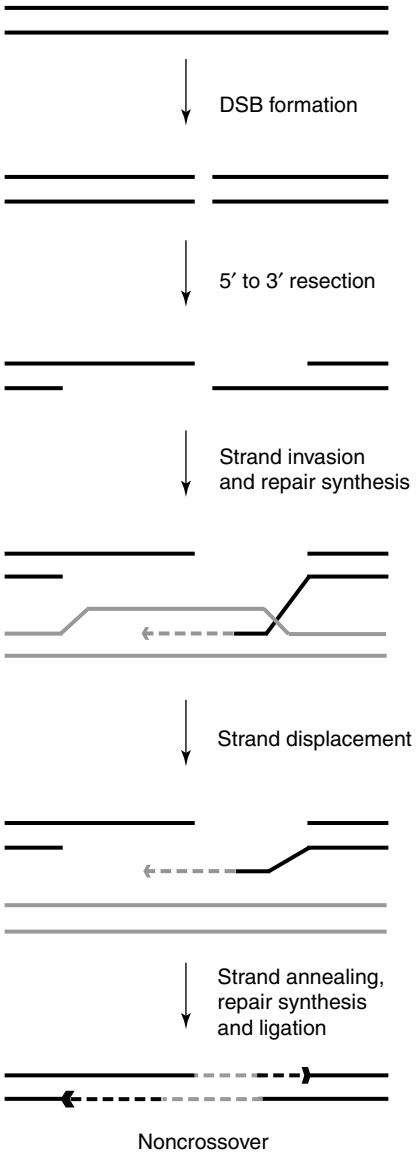


Fig. 3 Synthesis-dependent strand annealing (SDSA) model of homologous recombination. After induction of a double-strand break (DSB), both ends are resected to yield 3′ ends. The 3′ end invades a homologous sequence and primes repair DNA synthesis using the 3′ end and the invaded strand as template. After synthesis, the invading strand becomes displaced and anneals with the other 3′ single-strand tail of the processed DSB. This process differs from the DSBR in that the second end never is captured into the donor homologous duplex. The gaps in the annealed strand structure are filled in by repair synthesis, using the original strand as template. The reaction is completed by ligation of the nicks.

LOH events, and genetically are identical to products from mitotic crossing-over. The BIR process in yeast was initially called *break copy duplication*, based on the results from transformation with chromosome fragments. BIR may function in cells to maintain telomeres when the telomere replicating enzyme telomerase is absent. BIR can also result in nonreciprocal translocations if the broken end invades into homologous repeated sequences located on a different chromosome.

1.1.4 **Single-strand Annealing**

The last DSB repair process that uses homology to be discussed is single-strand annealing (SSA). SSA is thought to occur between directly repeated sequences (Fig. 5), but could also occur between sequences located on different chromosomes. In the SSA model, the ends of the DSB are resected to give 3′ tails, but these are not engaged in strand invasion of homologous sequences. Rather, the 3′ ends anneal to each other at the complementary single-stranded regions that have been revealed by the resection. The 3′ tails emanating from the annealed duplex are removed by endonucleases, and the nicks are then sealed by DNA ligase. SSA events are considered error-prone as they result in deletions between direct repeats, or potentially translocations and other rearrangements if sequences

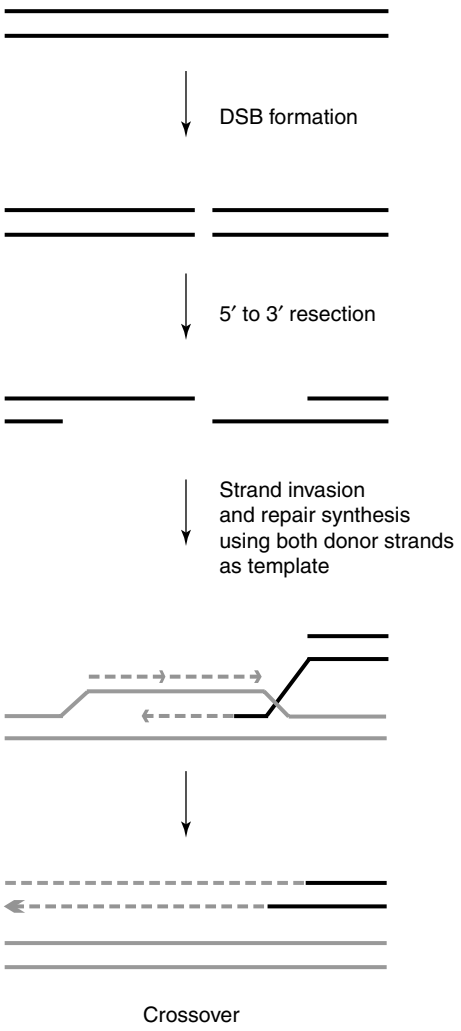

Fig. 4 Break-induced replication (BIR) model of homologous recombination. After induction of a double-strand break (DSB), both ends are resected to yield 3′ ends. The 3′ end invades a homologous sequence and primes repair DNA synthesis using the 3′ end and the invaded strand as template. The second end of the DSB is never engaged in the DSB repair reaction. DNA synthesis is established in the opposite direction, using the displaced D-loop as template. Synthesis continues to the end of the donor chromosome, copying both strands to repair the lost DNA sequence. The resultant product looks like half of a crossover reaction (see Fig. 1).

on different chromosomes anneal. Since SSA cannot occur without some type of chromosome rearrangement, it most likely is rare and usually involves direct repeats.

1.2 Nonhomologous End Joining

In addition to DSB repair using homology, cells also possess pathways to repair DSBs by nonhomologous methods. This type of repair is called *nonhomologous end joining* (*NHEJ*). NHEJ may use microhomologies of 1 to 2 nucleotides at the DSB ends, or there may be no homology at all. Ends are brought together by proteins specific for NHEJ, called *Ku70 and Ku80*. Additional factors essential for NHEJ include the protein kinase DNA-PKcs. Binding of these proteins to the DSB ends helps to bring the ends together. The ends are then ligated by a special ligase called *ligase IV* and its partner *XRCC4*. NHEJ is often error-prone and small deletions or additions occur at the ligated ends.

Although NHEJ is frequently error-prone, it is the major DSB end joining process used in mitotic cells in the G1 phase of the cell cycle. In G1, the only available homologous partner is the homolog chromosome, and pairing by a search for homology may be rate limiting when chromosomes are not naturally paired. Since only about 5% of the mammalian genome sequence encodes ORFs, error-prone end joining often may not be deleterious. During S phase and G2, the sister chromatid is available for repair

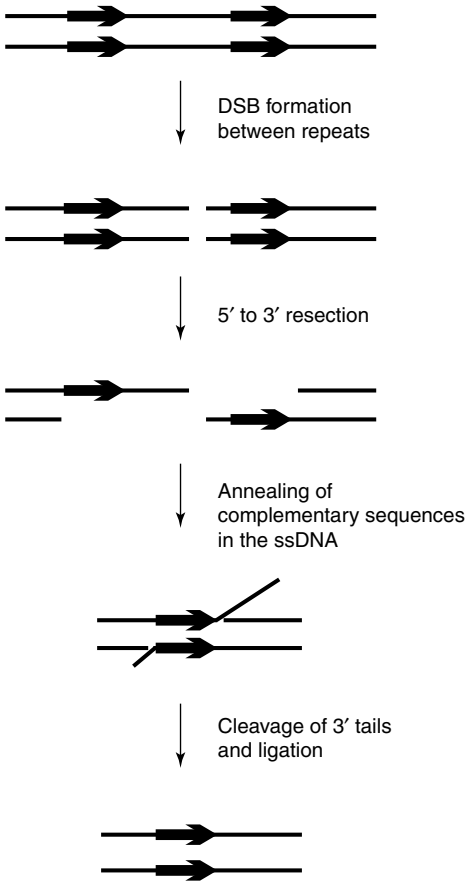

Fig. 5 Single-strand annealing (SSA) model of DSB repair. After induction of a double-strand break (DSB) between direct repeats, both ends are resected past the repeats to yield 3′ ends that have the repeat sequence in single-strand configuration. The complementary strand anneal at the repeat sequences, generating 3′ single-strand tails. The tails are cleaved by the structure specific Rad1/10 endonuclease (XPF/ERCC1 in humans), and the nicks are sealed by ligation. The SSA reaction results in a deletion of one copy of the repeat and the DNA sequence located between the repeats.

through HR and is held in close proximity through the cohesion complexes, which hold the sister chromatids together until mitosis.

NHEJ appears to be the preferred methods for repair of DSBs in vertebrate somatic cells. However, DSBs generated by sequence-specific endonucleases are often repaired by HR. Most HR proteins are essential and knockout mice for these proteins die as early embryos. This shows that HR is essential for repair of spontaneous damage during embryogenesis. The damage most likely occurs during replication, resulting in stalled or collapsed replication forks. Vertebrate cells that have nonlethal mutations in HR genes, such as Rad54, some of the Rad51 paralogs, or BRCA1, are sensitive to irradiation, showing that HR is also used to repair damage resulting from irradiation. NHEJ appears to be avoided in meiotic cells by downregulating the Ku proteins.

In yeast, NHEJ is used in the G1 phase of the cell cycle to repair DSBs while HR is used during late S and G2. NHEJ is also regulated through sequestration of the yeast XRCC4-like protein Lif1 to the cytoplasm in diploid cells that are able to undergo meiosis.

2
Steps in Homologous Recombination

In this section, the molecular mechanisms of the DSBR and SDSA models will be discussed, as these have been the most extensively studied of the HR mechanisms and are the most common DSB repair processes by HR. The proteins discussed are those used in eukaryotic systems. Most of these proteins are conserved from yeast to human. SSA usually occurs between direct repeats and appears to involve nucleolytic processing of the DSB, annealing of complementary strand promoted by the annealing activity of the Rad52 protein and RPA protein, processing of any nonannealed DNA tails by the ERCC1/XPF endonuclease, and sealing of the nicks by DNA ligase.

2.1
Initiation

Once a DSB is formed, to prepare the ends for HR, they must be resected to reveal 3′ single-strand tails. The resection most likely occurs through the action of the MRN complex and additional nuclease and DNA helicase activities. Once single-strand tails with 3′ ends are formed, these become coated with RPA protein to protect the single-stranded DNA and to remove any secondary structure. Next, RPA is displaced and Rad51 protein coats the single-strand DNA to form a DNA-protein filament. Rad51 loading is facilitated by a set of proteins related to Rad51 called the *Rad51 paralogs*, plus Rad52, and Rad54 proteins. Additional proteins related to Rad52 and Rad54 may also be involved. There are also a number of proteins that interact with Rad51 and may aid in the initiation stage of loading Rad51 or in the search for homology with a DNA partner. One important interactor is the Brca2 protein. Brca2 is mutated in some heritable human breast cancers and is clearly involved in HR. The DNA helicases WRN and BLM also are required in HR. Some models place these early in the initiation step, while other models propose that these helicases act during the later stage of resolution. The helicases could also act in the extension step, to open up the D-loop for extension of the invading 3′ end by replication.

The second step in initiation involves invasion of the intact donor DNA duplex by the 3′ Rad51 filament tail of the recipient DNA at a point of DNA homology, signaling the end of the search for homology and the beginning of strand invasion. Strand invasion is promoted by Rad54 protein and may also require Rad52 protein at the 3′ ends of the DSB. During strand invasion, the Rad51 protein is displaced from the 3′ single-strand region as this sequence enters into duplex-paired DNA. In the DSBR model, the displaced D-loop sequence is enlarged by extension of the 3′ end of the invading strand by replication. This requires leading strand DNA polymerases. Extension continues until the 3′ end completes the gap repair and can be ligated to the recessed 5′ end of the second DSB end. The second DSB end can also engage in a strand invasion of the D-loop, or be captured by extension of the D-loop until the displaced single strand of the D-loop can anneal with the other 3′ end of the DSB. In the SDSA model, the displaced D-loop sequence from the strand invasion is small and migrates, propagated by DNA synthesis.

2.2
Propagation

Propagation can be considered in two parts, extension of the 3′ end by replication,

and branch migration of the entire joint molecule. DNA synthesis from the invading 3′ strand appears to require the replicative DNA polymerases δ and ε (POL2 and POL3). It is not clear whether any of the error-prone translesion synthesis polymerases are also involved. HR is considered to be error-free as the DNA synthesis in replication uses the replicative DNA polymerases. However, some recent studies in yeast suggest that DSB repair by HR is more error-prone than replicative DNA synthesis. As described above, in the DSBR model, synthesis extends from the 3′ ends of the DSB until the gap is repaired and the ends can be ligated to the resected 5′ ends of the DSB, forming two HJs. In the SDSA model, synthesis proceeds only from the invading 3′ end, and continues until it is displaced from the template donor duplex. The newly replicated portion of the DSB is now able to base pair with the 3′ end from the other tail of the DSB, thus providing a template for synthesis from this 3′ end. When synthesis reaches the resected 5′ ends of the DSB, ligation can occur.

There is genetic evidence that a cross-strand DNA molecule with HJs can branch migrate. *In vitro*, the *E. coli* RecG DNA helicase and the *E. coli* RuvB helicase in association with RuvA can branch migrate a HJ. Both activities are required for normal HR in *E. coli*. Similar proteins have not been found in eukaryotes, although genetic evidence suggests that symmetric heteroduplex tracts can form during HR, and their formation is best explained by branch migration of HJs.

2.3 Resolution

Resolution in HR refers to resolution of the HJs. In the SDSA model, no HJs are formed and the repair products are always noncrossover. The DSBR model proposes the formation of double HJs. The search for proteins with endonuclease activity specific for HJ structures, producing products that can be ligated without errors has been ongoing for many years. In *E. coli*, the proteins that fulfill these criteria are the RuvC and RusA proteins. *In vitro*, RuvC cleaves HJs and *in vivo* it is required for HR. In eukaryotes, an endonucleolytic activity that is specific for HJs has been found to act on mitochondrial DNA. Loss of this activity has no effect on mitotic HR in chromosomal DNA or on meiotic HR. Recent studies point to a role for some of the Rad51 paralogs in HJ resolution activity. Alternatively, resolution of HJs could occur through the combined action of DNA topoisomerases and DNA helicases.

However resolution occurs, it must be able to resolve the HJs in a manner that allows the ends to be ligated together after cutting and the interlinked DNA strand to be untwined. Resolution may give crossover or noncrossover products, depending on which strands are cut, as shown in Fig. 2.

3 Regulation of Recombination

HR and NHEJ are the major DSB repair pathways. NHEJ is preferred in mammalian cells for DSB repair while HR is preferred in yeast. The consequences of deletion of NHEJ-specific factors in yeast are minimal, but in mammalian cells, loss of NHEJ results in increased HR. NHEJ and HR repair DSBs by different mechanisms, but have compensatory roles in maintenance of genomic integrity. Vertebrate cells defective in both NHEJ

and HR have high rates of genome instability and cannot be maintained as stable cell lines. There is greatly increased chromosomal aberrations and cell death. These observations show that spontaneous DSBs occur frequently enough to be lethal if unrepaired and that NHEJ and HR have overlapping roles in genome stability maintenance. Nonetheless, the use of NHEJ or HR to repair DSBs is regulated on several levels, including cell cycle regulation. NHEJ acts primarily in G1-early S for repair of both induced and spontaneous damage, while HR acts in late S-G2. This compartmentalization of the mode DSB repair helps to ensure that most HR DSB repair involves sister chromatid HR instead of interhomolog HR.

3.1 Meiosis versus Mitosis

Meiotic HR differs from mitotic HR in several aspects. These include the nature of the HR initiation events, the frequency of HR, meiotic-specific proteins involved in HR, the presence of the synaptonemal complex, the requirement for crossover HR events, preferential use of the homolog for HR, and the phenomenon of interference, which limits the number of crossovers per chromosome arm in meiotic HR.

While mitotic HR is essential for replication restart after fork stalling or collapse, meiotic HR is essential for proper chromosome segregation in meiosis I, through the occurrence of crossovers between homologous chromosomes. Thus, the ability of most organisms to produce euploid and viable meiotic products is dependent on HR. Most mitotic HR is initiated from spontaneous or exogenously induced DSBs. There are a few instances of programmed DSBs, including mating type switching in the fungi and V(D)J recombination in the immune system of vertebrates. Repair of these breaks occurs though a special program for each DSB system. In meiosis, HR occurs at induced DSBs, induced by action of the type II topoisomerase-like protein called *Spo11*. Spo11 DSBs occur at preferred chromosomal regions, which often have transcription initiation sites, but there is no specific DNA sequence that is recognized by any of the Spo11 proteins. Spo11-induced DSBs occur frequently enough such that the meiotic HR rate is at least 100-fold higher than the mitotic HR rate, and often is 1000-fold higher.

Mitotic HR occurs in the G2 phase of the cell cycle. Although there does not seem to be a specific structure required for mitotic HR, some chromosome scaffold or structure is required. Recent experiments show that DSB repair in G2 requires that chromosome cohesion, cohesion between sister chromatids, be established during S phase and be present in G2. Whether the cohesion complex helps direct most DSB repair by HR to interactions with the sister chromatid instead of the homolog is not known. In meiosis, in most eukaryotic organisms, the chromosomes become associated with a protein structure called the *synaptonemal complex* (*SC*). SC forms between homologous chromosomes. In yeast, DSB formation by Spo11 occurs prior to SC and the SC is thought to aid in homolog alignment. Recombination by the DSBR model occurs in the zygotene and early pachytene stages of meiosis. By pachytene, chromosomes are condensed and paired along their entire lengths, with SC. The SC dissolves in diplotene as chromosomes come apart in preparation for the first meiotic chromosome division.

The link between SC and HR is complicated as in some organisms SC formation is dependent on meiotic DSB formation, while in other organisms SC can form in the absence of DSBs. Nonetheless, mutations in SC components reduce meiotic HR, with resulting chromosome missegregation.

In addition to the meiotic-specific Spo11 protein and SC components, there are proteins that are required for meiotic HR that are expressed only in meiosis. Some of these include the homolog pairing proteins Hop1, Hop2, and Red1, a meiosis-specific Rad51 paralog called *Dmc1*, mismatch repair-like proteins called *Msh4* and *Msh5*, and a meiotic-specific checkpoint kinase called *Mek1*. These proteins are essential for meiotic HR, but have no detectable function in mitosis. Dmc1 does not substitute for Rad51 in the HR step of strand exchange, but does have strand exchange activity *in vitro*. Loss of Dmc1 results in arrest in meiosis during pachytene, without completion of HR. The arrest suggests that there is a checkpoint signal for incomplete HR. Some of the mitotic DNA damage checkpoint factors function in meiosis to ensure efficient repair of the meiotic DSBs by HR and arrest cells when DSBs are not repaired by HR. The Mek1 kinase appears to regulate DSB repair through Dmc1. Msh4 and Msh5 are related to the mismatch repair proteins MutS of *E. coli* and Msh2 of yeast. However, Msh4 and Msh5 do not function in mismatch repair. Rather, they are essential for crossing-over in meiosis and loss of Msh4 or Msh5 in mice results in aberrant meioses and sterility. Msh4 and Msh5 act with the mismatch repair protein Mlh1 in meiosis in this pathway.

Most mitotic DSB repair that produces genetic recombinant products is of the gene conversion type without any associated crossing-over. This observation led to the development of the SDSA model. In contrast, about half of the meiotic genes conversions are associated with crossing-over. This observation was crucial in the development of the DSBR model, with resolution of the HJs as crossover or noncrossover. However, recent studies on the timing of molecular intermediates in meiotic HR in yeast have shown that noncrossovers occur before crossovers. This has led to the suggestion that there are two types of meiotic HR pathways. The first is dedicated to noncrossovers and occurs by the SDSA model for gene conversions. The second pathway occurs slightly later through the DSBR model. Resolution of the HJs results in crossovers. The suggestion is that all noncrossovers come from SDSA HR while crossovers come from DSBR, which has HJs. Moreover, the HJs are always resolved to give crossovers. Both the SDSA and DSBR models involve formation of heteroduplex DNA, which is a substrate for the mismatch repair proteins. Mismatch repair occurs whenever DNA mismatches arise. In mitotic growth, most mismatches occur from errors during DNA replication where an incorrect nucleotide is used, resulting in a base-pair mismatch. If the mismatch is not corrected by the editing function of the DNA polymerase, it becomes a target for the mismatch repair proteins. Mismatch repair is an essential step in recombination, correcting the heteroduplex that has formed between two recombining DNA strands. In the absence of mismatch repair, mutations will accumulate and the strains will have a mutator phenotype. The strains are able to undergo recombination, but maturation of the heteroduplex is defective.

3.2
Sister Chromatid Recombination versus Homolog Recombination

Sister chromatid recombination can only occur in late S or G2, after chromosomes are replicated. As the recombination occurs between identical DNA duplexes, there is no genetic signal for its occurrence. Sister chromatid recombination can be detected genetically when it occurs out of register within a duplication or a multiple

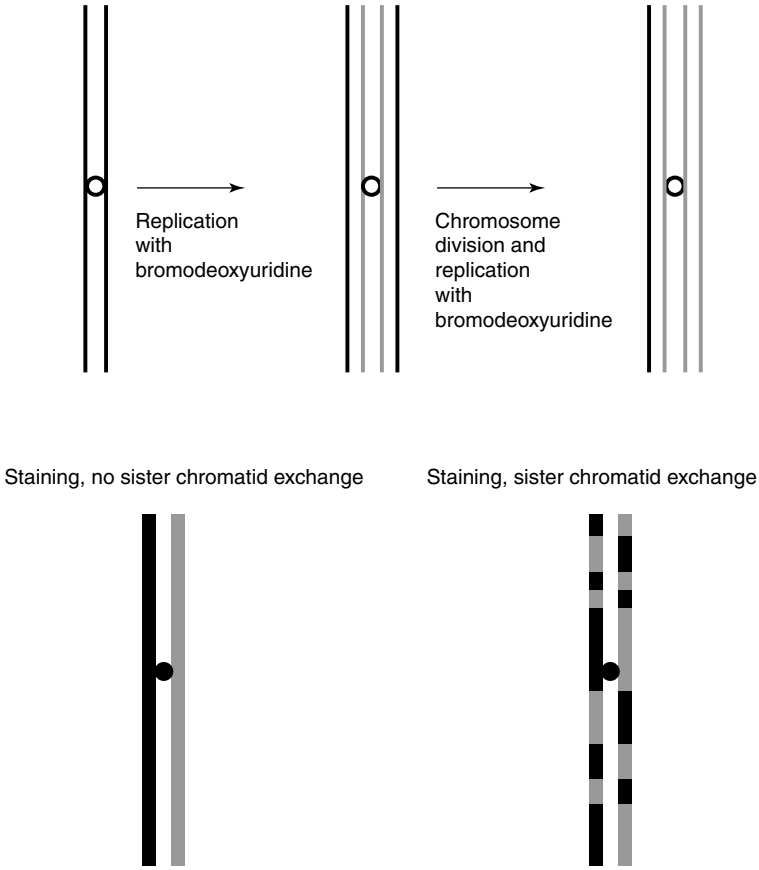

Fig. 6 Cytological detection of sister chromatid exchange. Cell is grown for two rounds of replication in the presence of the nucleotide analog bromodeoxyuridine. After one round of replication, the chromatids are hybrid, with one substituted and one unsubstituted DNA strand. After the second round of replication, cells are arrested in mitosis. The chromosomes have one fully substituted chromatid and one hemi-substituted chromatid. Differential staining of the fully substituted and hemi-substituted chromatids results in a microscopic light/dark pattern, with the fully substituted chromatid being light colored. If no sister chromatid exchange has occurred, then one chromatid is fully dark while the attached sister chromatid is fully light. If sister chromatid exchange has occurred, each chromatid will show an alternating pattern of light and dark regions, and the two attached chromatids are mirror images of each other.

tandem repeat. Assays using duplications have been devised to detect unequal sister chromatid exchange (Fig. 6). Alternatively, sister chromatid recombination can be detected visually in vertebrate cells using chromosome staining methods. Cells are allowed to go through two rounds of replication with a nucleotide substitute of bromodeoxyuridine for thymidine. Cells are then arrested in mitosis with a microtubule inhibitor, so that cells will have replicated chromosomes with both sister chromatids still attached at the centromere. The chromosomes are stained with a fluorescent dye, which reveals the bromodeoxyuridine incorporation, and Giemsa stain for the chromosome regions that do no have bromodeoxyuridine. If no sister chromatid exchange has occurred, the chromatid with both strand containing bromodeoxyuridine will be light colored while the chromatid with one substituted strand will be dark colored. Where sister chromatid exchange has occurred, a single chromatid will contain both light and dark sections, and this alternates with the light/dark staining pattern of the sister chromatid. Such chromosomes are called *harlequin chromosomes*.

Using the harlequin assay, it has been found that spontaneous sister chromatid exchange requires HR proteins, but not NHEJ proteins. DNA damage induced sister chromatid exchanges also required HR proteins, showing that sister chromatid HR is important for DSB repair and damage avoidance. In fact, a hallmark of some human diseases that are defective in the correct response to DNA damage is increased sister chromatid exchange. The defect probably lies in an inability to regulate repair by nonrecombinogenic pathways at stalled replication forks.

Since most mitotic HR between homologs is gene conversion that is not associated with crossing-over, one might expect the same to be true for sister chromatid recombination. Using a recombination substrate consisting of a marked duplication with a site-specific DSB to induce the HR, it has been found that most DSB repair uses the sister chromatid as a template for repair, and that most sister chromatid recombination is in fact gene conversion, not exchange. This is consistent with an SDSA model for sister chromatid recombination and consistent with the observation that crossing-over, either between homolog chromosomes or sister chromatids is infrequent in mitotic cells, even in the presence of DSB damage.

If most DSB repair occurs between sister chromatids, how is the meiotic HR program modified to promote interhomolog HR? Part of the answer must lie in meiotic-specific proteins that promote interhomolog HR. Some of these include the meiotic-specific chromosome cohesion protein Rec8, the SC structure itself, and a newly recognized protein called *Mnd1*, which is proposed to promote close homolog juxtaposition in preparation for strand exchange.

3.3 Regulation by Cell Cycle DNA Damage Checkpoint Factors

DNA damage is sensed by cell cycle checkpoint factors that recognize unrepaired DSBs. One important signal in the checkpoint response is single-strand DNA coated with the single-strand DNA binding protein RPA. DNA damage checkpoint factors bind to unrepaired DSBs and set off a cascade of signal transduction through protein kinases that modify components of the replication and recombination repair machinery and arrest cells in the G2 phase of the cell cycle until damage has

been repaired. At this point, the arrest is reversed and cells resume growth and proceed through mitosis to the next cell cycle. In mammalian cells, apoptosis is also a response to unrepaired DSBs. Key proteins in the checkpoint response are the ATM (ataxia-telangiectasia mutated) and ATR (ATM and RAD3-related) protein kinases, which transduce the damage signal and phosphorylate many proteins involved in DNA repair, recombination, replication transcription, and cell cycle progression.

3.4 Alternative Repair Pathways

As has been discussed in Sects. 1.1 and 1.2, there are multiple DSB repair pathways in eukaryotic cells, some of which do not involve HR. However, not all spontaneous damage originates as DSBs. DSBs may arise from processing of stalled replication forks, but the initial damage may be single-strand DNA gaps at the fork. There is overlap in the pathways used for repair of spontaneous damage. Evidence for this comes from several sources. First, genetic studies in yeast have revealed several genes that function in alternative repair pathways for damage associated with stalled replication forks. One of these pathways involving the yeast *MPH1* gene also requires HR gene functions. However, loss of Mph1 function does not affect HR. Mph1 functions in error-free bypass of DNA lesions, in a manner that also requires HR. This most likely involves sister chromatid interactions, possibly some type of template switching, which requires strand invasion of the sister chromatid to synthesize past DNA lesions.

The second set of observations on repair pathways that overlap with HR comes from studies of chicken DT40 cells. The HR mutant RAD54 (−/−) is viable, but sensitive to ionizing radiation and defective in DSB-promoted HR assays. RAD18 is a key gene in the translesion synthesis repair, to fill in gaps on the daughter strands caused by lesions in the template strands during replication. The mutant RAD18 (−/−) is viable, but sensitive to UV radiation. The mutant has a great increase in sister chromatid exchange events, suggesting that damage normally repaired by RAD18 is now repaired by the HR pathway. The double mutant Rad54 (−/−) RAD18 (−/−) is lethal. These types of experiments highlight the cross talk between different repair modes of the cell.

4 Consequences of Defects in Homologous Recombination

4.1 Rearrangements Associated with Mutations in HR Genes

In yeast, the HR gene mutants are viable. Haploid HR mutants, in addition to reduced HR rates, are associated with increased genomic instability and deletions, translocations, and telomere fusions. Many of the rearrangements have breakpoints with no homology or microhomology. These rearrangements are similar to those observed in cancer cells, suggesting that defective HR results in the types of chromosome aberrations seen in tumor cells. Diploid HR mutants have chromosome loss as the most frequent type of chromosome aberration, although the aberrations listed above also arise, but at much lower frequencies than chromosome loss. These findings show that HR is essential for genome stability maintenance.

In vertebrate cells, many HR mutants are not viable. However, examination of

early embryonic cells has revealed massive chromosome rearrangements. Mutants in the RAD51 paralog genes are associated with chromosome and chromatid breaks. In the chick DT40 system, it has been possible to make conditional RAD51 mutant cells. These mutants have very high levels of spontaneous chromosome breaks and have increased sensitivity to DNA damaging agents.

BRCA2-deficient cells accumulate several different types of chromosome rearrangements and aberrations. Most prevalent are chromosome breaks, chromatid breaks, end-to-end fusions of chromosomes, translocations, and deletions, and chromosomes with multiple arms that appear to result from multiple aberrant recombination reactions. Similar chromosome aberrations have been seen in RAD51-deficient cells. The overlap in phenotypes is expected given that BRCA2 and RAD51 function together at an early stage in HR. The finding that the rearrangements occur spontaneously underscores the importance of HR in maintaining genomic stability in growing cells, repairing lesions that occur during DNA replication.

4.2 Meiotic Defects Associated with Mutations in HR Genes

Meiotic phenotypes associated with defects in HR genes have been seen only in mutants of genes that are either only expressed in meiosis or genes that have milder HR consequences in mitosis. In yeast, the HR mutants are mitotically viable, although they are associated with decreased HR and increased genomic instability and chromosome rearrangements. In meiosis, the same mutants fail to complete meiosis and give no viable meiotic products. Thus, these mutants are meiotic-inviable, but mitotic-viable. There exists another set of mutants in meiotic-specific genes such as *SPO11*, *DMC1*, *MSH4*, and *MSH5* plus genes encoding subunits of the synaptonemal complex. Mutants in these genes give no viable meiotic products, or a reduced number of viable meiotic products with aneuploid karyotypes. In the mouse, *SPO11*−/− mutants are infertile, have synapsis defects cells undergoing meiosis, and apoptosis is increased in the spermatocytes and ooctyes cells.

In vertebrates, most HR mutants are not mitotically viable. Most work has focused on the meiotic-specific genes. Mutants in these genes are associated with aberrant chromosome structures in meiosis and infertility, consistent with the essential role of HR in meiotic chromosome segregation.

5 Concluding Remarks

In the past few years, our understanding of HR models, proteins, and regulation has been elevated by quantum leaps. It is now appreciated that HR occurs by distinct mechanisms, even with the same initiating substrate of a DSB. Most mitotic HR occurs by SDSA, and in fact most mitotic HR probably occurs between sister chromatids, not between homologs. Meiotic HR occurs by SDSA and DSBR, with the two types of HR occurring with different timing in a meiotic program that carefully regulates the number and spacing of crossovers. Most meiotic HR occurs between homologs, in contrast to mitotic HR.

Although some of the HR proteins are related, such as RAD51 and DMC1, and RAD54 and RAD54B, each protein has a distinct role in the HR process. The

number of accessory proteins seems to be increasing to include DNA damage checkpoint factors. One aspect of HR that remains controversial is the eukaryotic resolvase. While resolvase activity has been identified in cell extracts and found to be missing from mutant cell extracts, the resolvase protein has not yet been definitively identified.

The importance of HR is underscored by the finding that HR is essential for all dividing cells. Given its essential role, it is not surprising that there are few human diseases associated with mutations in the genes required for the HR process itself, such as the *RAD51* gene. However, there are rare cases of mutations in genes that encode proteins that are mediators of HR or are checkpoint proteins for the DNA damage response pathway. These include ATM, leading to ataxia-telangiectasia, NBS1, leading to Nijmegen breakage syndrome, ATR, leading to Sekel syndrome, BLM, leading to Bloom syndrome, WRN, leading to Werner syndrome, MRE11, leading to AT-like disease, the FA genes, leading to Fanconi anemia, BRCA1 and BRCA2, leading to breast cancer. Most of these diseases are associated with increased cancer risk, and on the cellular level, there is increased genomic instability and defective repair of DNA damage, including DSBs. Understanding how these HR defects result in genomic instability is the first step in being able to limit the damage caused by genomic instability.

Keywords

Alternate Splicing
When a single gene after splicing gives rise to more than one mRNA sequences. It may be due to joining of exons in different series. Sometimes, HnRNA may splice differently (a portion of sequence may act as intron in one case and as exon in other case).

Attenuation
A mechanism to control RNA polymerase to read through an attenuator, an intrinsic termination sequence present at the beginning of the transcription unit. This type of control is present in some prokaryotic operons.

CAAT Box
A conserved sequence located nearly 75 nucleotides upstream of the start point of transcription units found in eukaryotes, also called as −75 box sequence. It is recognized by certain transcription factors. It has the consensus sequence GGCAATCT. It plays an important role in increasing the promoter strength.

Cyclic AMP Receptor Protein (CRP or CAP)
A regulatory protein activated by 3′,5′ cyclic AMP (cAMP). In prokaryotes, transcription of many genes gets activated after binding of this protein (in the form of CRP–cAMP complex) on a specific site in the DNA. Two molecules of cyclic AMP bind with one molecule of CRP.

Exon
A segment of interrupted gene having coding region and present in mature mRNA.

Gratuitous Inducer
A substance that induces the transcription of a gene(s) but is not a substrate for its enzyme protein product. Generally, it is an analog of the substrate, a normal inducer.

Intron or Intervening Sequence
A segment of interrupted gene found in eukaryotes. Intron gets transcribed but do not code for a protein product. Intron sequence gets removed during maturation of primary transcript, a process called as RNA splicing.

Inducer
A small molecule that triggers biosynthesis of RNA by binding to the cytoplasmic repressor (product of a regulatory gene). It is generally the substrate of the enzyme protein product of the structural gene.

Induction
The ability of bacteria or yeast to synthesize certain enzymes only when their substrates are present. The inducer binds to the cytoplasmic repressor preventing it from binding to the operator region. If cytoplasmic repressor is already bound with the operator, it gets detached from the operator region after binding with the inducer.

Lariat
An intermediate formed during RNA splicing where a circular structure with a tail is formed by a 5′,2′ bond.

Leader Sequence
A nontranslated sequence at the 5′ end of mRNA preceding the initiation codon.

Operator
A DNA sequence to which cytoplasmic repressor (protein product of regulatory gene) binds specifically.

Polyadenylation
The addition of Poly A sequence to the 3′ end of an eukaryotic RNA (a posttranscriptional change).

Polycistronic mRNA
An mRNA having the information for more than one protein. It forms after transcription of more than one gene present in a cluster (operon).

Promoter
The region of DNA involved in the binding of RNA polymerase to start RNA biosynthesis.

Regulatory Gene
This gene codes for an RNA or a protein that controls the expression of other genes.

Repression
Inhibition of enzyme biosynthesis by a product of the metabolic pathway. Generally, inhibition is at the level of transcription. The product of the regulatory gene (cytoplasmic repressor) and the product of the metabolic pathway (corepressor) complex binds to the operator region on the DNA.

Ribozyme
RNA as an enzyme. Some RNA molecules are capable of self-RNA splicing without involvement of any protein. This type of RNA is called as ribozyme.

SnRNAs (Small Nuclear RNAs)
These are small RNAs present in the nucleus and are considered to be involved in RNA splicing/other processing reactions.

SnRNPs
Are small nuclear ribonucleoproteins. In these, SnRNAs are associated with proteins.

Splicing
Removal of introns and joining of exons in RNA.

TATA box
A conserved sequence found about 25 nucleotides upstream from the start point of eukaryotic RNA polymerase II transcription unit. It is considered to be involved in positioning RNA polymerase II for correct initiation.

Telomerase
Is an enzyme resembling reverse transcriptase. Telomerase enzyme adds telomeres to chromosome ends.

Telomere
Are the specialized structures at the ends of linear eukaryotic chromosomes. They generally have many tandem copies of a short oligonucleotide sequence, T_aG_b in one strand and C_bA_a in the complementary strand, where a and b are on an average 1 to 4.

Upstream
The sequences found at the 5′ end of and beyond the region of expression.

The central dogma in gene expression is ''DNA makes the RNA, a process called as transcription; and RNA makes the protein, called as translation.'' Gene expression can be regulated at the stage of transcription, RNA processing (post-transcriptional changes), and translation. Organisms have been classified into two groups – Prokaryotes whose cells do not have distinct well-defined nucleus, and eukaryotes whose cells have distinct well-defined nucleus. Examples of prokaryotes are bacteria and the blue green algae and of eukaryotes are animals, plants and fungi. In prokaryotes, the RNA primary product may itself be the target of regulation. In eukaryotic cells, due to compartmentation, transport of mRNA from the nucleus to the cytoplasm could be an additional target for regulation. However, bacterial mRNA is directly available for protein biosynthesis soon after its synthesis. Regulation of transcription usually occurs at the stage of initiation. The regulators of initiation of transcription may be a protein or RNA. In prokaryotes, on–off of transcription is the main regulatory control of the gene expression, whereas, in eukaryotes, more complex regulatory mechanism of transcription takes place. In addition, RNA splicing also plays major role in the regulation of gene expression. Here, it is pertinent to mention that eukaryotic genes have been found to have coding as well

as noncoding sequences. In fact, as per recent human genome sequence data, more than 50% sequences are noncoding sequences whose function is also not clear. These are called *introns* or junk sequences. The coding sequences are called *exons*. Of course, there are regulatory elements too. The primary transcript of DNA has complementary sequences of both exons and introns and is called heterogenous RNA (HnRNA). The HnRNA gets spliced removing introns and ligating exons. Regulation of gene expression in both prokaryotes and eukaryotes is important since it decides whether a particular protein should be synthesized and in which quantity.

1 Regulation of Gene Expression in Prokaryotes

1.1 Induction and Repression

In prokaryotes, induction and repression especially in enzyme proteins is the prominent way of regulation at the level of transcription. There are certain proteins that are synthesized at constant rate at all the times. There are certain proteins, especially the enzymes, that are produced in larger amounts in the presence of certain substances. The substance, which is generally the substrate of the enzyme protein, enhances an enzyme's synthesis and is called an *inducer*, the enzyme is called as *inducible enzyme*, and the process is known as *enzyme induction*. It is not necessary for the inducer to be the substrate of the enzyme. The inducer may resemble the natural substrate and need not necessarily be affected by it. An inducer that is not the substrate of the enzyme is called *gratuitous inducer*. An inducer may induce more than one enzyme whose genes are arranged in cluster.

An inducible enzyme is normally present only in trace amounts in a bacterial cell, but its concentration can quickly increase even a thousand fold or more when its substrate is present in the medium particularly when this substrate is the only carbon source of the cell. Under these conditions, the induced enzyme is required to transform the substrate into a metabolite that can be utilized by the cell directly. A well-studied example of inducible enzyme is of β-galactosidase from *Escherichia coli*. The *E. coli* cells having wild type β-galactosidase gene do not utilize lactose if glucose is also present in the medium. If only lactose is present as sole carbon source or after the complete utilization of glucose, within one to two minutes the cells synthesize β-galactosidase enzyme and start utilizing lactose. Simultaneously, there is synthesis of β-galactoside permease, which is required for the transfer of β-galactoside inside the bacterial cell and also of β-thiogalactoside transacetylase. If the induced bacterial cells are transferred into a medium deficient in lactose, synthesis of β-galactosidase (along with β-galactoside permease and β-thiogalactoside transacetylase) ceases immediately and the previously induced enzyme also gets declined to a normal level. Induction of a group of related enzymes or proteins to the same extent by a single inducing agent is known as *coordinate induction*. Here, induction of β-galactosidase along with β-galactoside permease and β-thiogalactoside transacetylase is an example of coordinate induction.

Earlier, two hypotheses were given to explain the mechanism of enzyme induction using the β-galactosidase system:

1. Activation of preexisting protein occurred.
2. *De novo* synthesis of the protein occurred.

The first possibility was discounted because of the reason that, prior to induction, no protein could be detected having antigenic property similar to β-galactosidase. This observation suggested that actual synthesis of the enzyme protein occurs after addition of the inducer. At that time, scientists were knowing that specific protein will not be synthesized except in the presence of gene which dictates its primary structure (amino acid sequence). From the observations, it was also clear that *E. coli* cells carry structural gene for β-galactosidase enzyme protein. Thereafter, the question remained as to why β-galactosidase enzyme protein synthesis did not occur in the absence of inducer. For this question, again the following two explanations were considered:

1. It may be considered that inducer acts as some sort of template that triggers the enzyme protein synthesis. It was thought that because of this reason the inducer resembles the substrate.
2. It is possible that enzyme protein is not synthesized because of inhibition by some agent(s). In this case, the inducer itself may act as some sort of inhibitor, which inhibits the activity of inhibiting agent(s). This possibility seems to be very complex, but afterward, evidence became available in support of this hypothesis and now we know that this is what actually occurs.

Similarly, in the presence of a substance that is the product of a particular enzyme reaction, the synthesis of an enzyme protein can be reduced. This phenomenon is called *enzyme repression* and the substance is called *corepressor*.

Induction and repression are two complementary phenomena. Generally biosynthetic pathways have been found under the control of repression. Many amino acids biosynthetic pathways are found to be under the control of repression. For example, if histidine is added to *E. coli* growth medium, all the enzymes involved in its biosynthesis no longer are synthesized since cells do not require to synthesize histidine. In the presence of histidine, all the enzymes required for the biosynthesis of histidine starting from ATP phosphoribosyl transferase, which catalyzes the first reaction in the histidine biosynthetic pathway (biosynthesis of phosphoribosyl ATP from phosphoribosyl pyrophosphate and ATP), are repressed. Such repression of the synthesis of a group of enzymes by a single corepressor is called *coordinate repression*. Coordinate repression is generally caused by the end product of the biosynthetic pathway, and, because of this reason, it is also called *end product repression*.

1.2 The Operon

Jacob and Monod in 1961 gave the concept of operon. They explained that genes encoding proteins whose functions are related, such as the consecutive genes proteins in a pathway, may be organized in a cluster that is transcribed into a polycistronic mRNA from a single operator and control of this operator regulates gene expression of the entire structural genes in the operon. The unit of regulation containing structural genes, regulator gene(s), and cis-acting elements is called *operon*. The genes may be classified into

two groups depending on their coded protein functions: *structural genes* whose protein products are directly involved in the metabolic activity (act as enzymes) or act as constituent of an organelle and the *regulatory genes* whose products regulate the transcription of the structural genes. The activity of an operon is controlled by the regulatory gene(s) whose protein product interacts in its control elements. Although many operons have been studied in detail, one of the most-studied examples of operon is *lac* operon of *E. coli*. In *lac* operon, *lac* i is the regulatory gene whose protein product called as cytoplasmic repressor is involved solely in regulation, while *lac* Z, *lac* Y, and *lac* A are structural genes which code for the enzymes, β-galactosidase, β-galactoside permease, and β-thiogalactoside transacetylase, respectively. The *lac* operon is described below.

1.3 The Lactose Operon (*Lac* Operon)

If *E. coli* cells are grown in a medium containing lactose as a sole carbon and energy source, the cells will synthesize the enzymes, β-galactosidase (which catalyzes the hydrolysis of lactose into glucose and galactose), β-galactoside permease (which allows lactose to enter the cell) and β-thiogalactoside transacetylase (which catalyzes the transfer of acetyl group from acetyl CoA on to 6 position of β-thiogalactoside to form 6-acetyl β-thiogalactoside). Glucose is easily metabolized and directly enters the glycolytic pathway. Galactose must be converted into glucose before it enters the glycolytic pathway. Studies with the *lac* operon showed that it consisted of three adjacent structural genes *lac* Z, *lac* Y, and *lac* A. Preceding these genes are *lac* O, *lac* P, and *lac* i, involved in regulation. *Lac* i codes for a protein called as cytoplasmic repressor. *Lac* P is the promoter site on which RNA polymerase binds. *Lac* O is the controlling site on which cytoplasmic repressor binds and after binding, there is switch off of transcription of the structural genes (Fig. 1). All the three structural genes are transcribed as a single polycistronic messenger RNA carrying genetic information for all the three enzyme proteins. Besides lactose, many other analogs such as isopropyl-β-thiogalactoside (IPTG), methyl- β-thiogalactoside, and mellibiose also act as inducers. *In vitro*, the most commonly used inducer for *lac* operon is IPTG.

The genes located in the *lac* operon are:

Gene Z^+ (*lac* Z^+): this gene in mutant condition results in the loss of ability to synthesize active β-galactosidase either in the presence or absence of inducer.

Gene Y^+ (*lac* Y^+): this gene in mutant condition results in the loss of ability to synthesize active β-galactoside permease either in the presence or absence of inducer.

Gene A^+ (*lac* A^+): this gene in mutant condition results in the loss of ability to synthesize active β-thiogalactoside transacetylase either in the presence or absence of inducer.

Gene i^+ (*lac* i^+): this gene causes changes in the influence of inducer on the synthesis of β-galactosidase, β-galactoside permease, and β-thiogalactoside transacetylase.

Many i mutants synthesize large amount of the enzymes in the absence of inducer. Using different combinations of wild type and mutant genes of *lac* Z, *lac* Y and *lac* i genes, different types of genetic structures

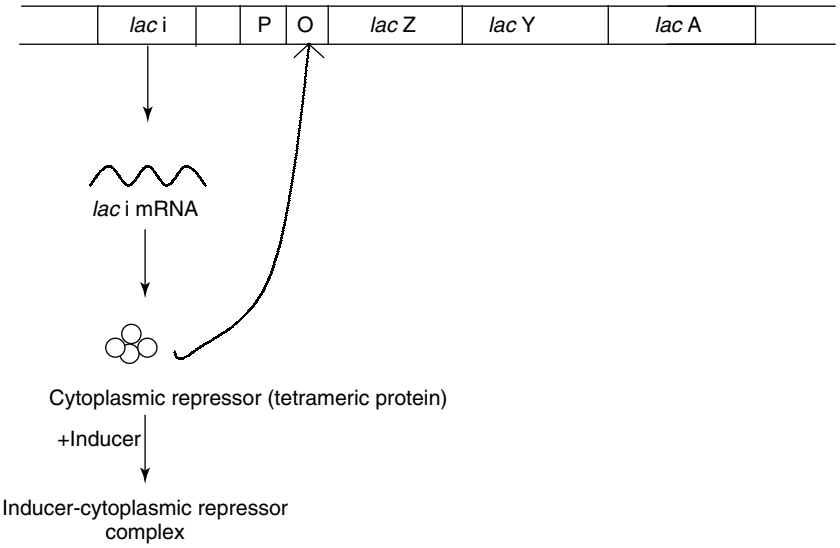

Fig. 1 Line diagram of *lac* operon: P, promoter; O, operator; *lac* i, regulatory gene; *lac* Z, Y, and A, structural genes for β galactosidase, β galactoside permease, and β thiogalactoside transacetylase, respectively. RNA polymerase binds on the promoter site. Cytoplasmic repressor binds on the operator site and represses transcription of the structural genes (negative control). In the presence of the inducer, there is formation of inducer-cytoplasmic repressor complex, which is not capable of binding on the operator site. If already cytoplasmic repressor is bound on the operator site, it gets detached from there after making a complex with the inducer, resulting in transcription of the structural genes.

Tab. 1 Various genotypes of the *E. coli* lactose system.

Genotype	***Noninducible***		***Inducible***

$Z^+ Y^- i^-$	+	−	+	−
$Z^- Y^- i^-$	−	−	−	−

of *lac* region of *E. coli* chromosome may be assumed (Table 1).

Regulatory gene(s) need not necessarily be located near the structural genes. Its action is due to the biosynthesis of some intracellular substance or substances. Study of mutation in the regulatory gene provided insights into the main mechanism

of induction and repression. Mutated *lac* i gene is called as *lac* i^-. The *E. coli* cells containing i^+ produce β-galactosidase only in the presence of inducer whereas cells containing mutated *lac* i can produce β-galactosidase both in the presence and absence of inducer. These results indicate that *lac* i^+ is dominant and *lac* i^- is recessive.

Regulatory gene, *lac* i^+ codes for a protein called as cytoplasmic repressor or *lac* repressor. It is a tetrameric protein having four identical subunits of the molecular weight, around 37 000. This protein specifically binds on the operator region. Each subunit is a chain of 347 amino acids. The N-terminal amino acid is methionine and C-terminal is glutamine. The tetrameric protein may be dissociated in the presence of sodium dodecyl sulfate. Each individual subunit has one binding site for inducer. The individual subunits also have the ability to bind inducer but are not able to bind on the operator region. The binding constant for IPTG has been calculated to be about 10^{-6} M. The cytoplasmic repressor binds very tightly with the operator region. The equilibrium constant of the complex is about 10^{-13} M. The rate constants for association and dissociation are $7 \times 10^9\ M^{-1}\ sec^{-1}$ and $6 \times 10^{-4}\ sec^{-1}$, respectively. Although, there is normal content of various amino acids, tryptophan content is comparatively low. There are only two tryptophanyl residues out of 347 amino acids in a subunit. The $OD_{280}^{1\%}$ is 0.59 (comparatively low value due to low contents of tryptophan).

Using circular dichroism and optical rotatory dispersion studies, an estimate of about 33 to 40% α-helix contents and 18 to 42% β-structure has been made. Using Chou Fasman model, from the primary sequence, a prediction of 37% α-helix contents and 35% β-structure has been done. Both the data are in the same range.

Using electron microscopy after negative staining and powder X-ray diffraction analysis, an asymmetric dumbbell-shaped tetramer of the dimensions about 45 Å by 60 Å with four tetramers contained in one unit cell of 91 Å by 117 Å has been found. Powder X-ray diffraction patterns indicated that the third unit cell dimension, which is not seen in electron micrographs, is 140 Å. Four tetramers can easily be packed into this cell, in a manner that accounts for the stain distribution observed in electron micrographs. The molecule extends the full length of the 140 Å cell and gives the tetramer an elongated shape having approximately molecular dimensions of 140 Å by 60 Å by 45 Å. On the basis of these data, a model has been proposed in which the subunits are related by 222 symmetry and are placed at the corners of a rectangular plane. This suggests the existence of two operator binding sites per tetramer if the repressor maintains perfect 222 symmetry.

However, the shape of the *lac* repressor in solution appears quite different. In solution, the repressor tetramer appears as a square structure with dimensions of about 105 Å by 95 Å, and the shape as well as dimensions of the molecule does not change in the presence of IPTG. The subunits can be distinguished in tetrameric structure, however, due to poor resolution, no decision on the geometry of their arrangement could be taken.

It looks that there should be two different types of binding sites in the tetrameric structure: the first for the small molecular-weight effectors and the second for the *lac* operator. There are indications that both inducers and antiinducers bind to the same site, or at least to overlapping sites. *O*-Nitrophenyl β-D-fucoside has been

found to act as anti-inducer for *lac* operon. Similarly, the operator binding site involves the same region of the tetrameric repressor that binds nonoperator DNA. Each repressor subunit looks to have an effector binding site besides contributing some interactions with operator DNA. On the basis of experiments, it has been concluded that the effector binding site and operator binding site are distinct and nonoverlapping. On the basis of trypsin limited digestion studies which splits 59 amino terminal residues and 20 carboxyl terminal residues of each subunit, leaving a tetrameric trypsin resistant core protein made up of subunits having 60 to 327 residues, it has been shown that the amino and carboxyl terminal residues are neither required for the binding of inducer nor for the folding of the subunits into proper tetrameric conformation. However, it could not be confirmed whether the interaction between the subunits of the core is identical to the interaction of the subunits in the native repressor. There are indications that terminal regions are involved in operator binding. There are also indications that effector binding changes the affinity of the repressor for its operator. Both amino and carboxyl terminal regions have hydroxyl group containing amino acids (threonyl residues at position 5, 19, 34, 315, 316, 321, 323; seryl residues at position 16, 21, 28, 31, 309, 325, 332, 341, 345) which could contribute their hydroxyl groups of side chains to form hydrogen bonds with specific groups of the bases in the *lac* operator. Out of total 8 tyrosyl residues in the chain, there are four residues in the 59 residues amino terminal region (at position 7, 12, 17, 47), which offer the possibility of interactions with DNA either by providing additional hydroxyl groups or by intercalation between the bases. Besides, eight positively charged amino acids have been found in the 59 amino terminal region and six positively charged residues in the 36 carboxyl terminal region. It is the higher content of positively charged amino acids in the terminal regions (14.7%) compared to total percentage in the molecule (10.7%). It has been considered that the combination of the amino and carboxyl terminal regions constitute a basic region which through electrostatic interactions make contact with the negatively charged DNA and contribute to its specific binding to operator region. The region between 215 and 324 amino acyl residues has few charged residues (only 3 each positive and negatively charged residues) and is enriched in hydrophobic residues, therefore, it may involve in the stabilization of both the native tetramer and its tryptic core. This region may act as a hydrophobic nucleus resistant to trypsin attack.

The *lac* repressor can make four types of interactions:

1. Specific interaction between *lac* repressor and its operator
2. Nonspecific interaction between *lac* repressor and any DNA
3. Specific interaction between *lac* repressor and its small molecular weight effectors, which include inducers, antiinducers
4. The effector (inducer) may also interact with the *lac* repressor already bound to the operator to form an intermediate ternary complex.

One molecule of inducer IPTG is found to be sufficient to release the *lac* repressor from its specific operator. After binding of the inducer, there is nearly 1000-fold decrease in the affinity of the repressor for its operator. *Lac* repressor shows a single emission maximum at

338 nm in fluorescence spectrum, which is characteristic of tryptophan. On addition of inducer in saturating concentrations, there is a shift in emission maximum to 330 nm with no change in peak shape and also fluorescence intensity. This change in the emission maximum suggests that at least one tryptophanyl residue per subunit becomes less accessible to the solvent upon inducer binding. No change in the shape of the fluorescence spectrum indicates that either both tryptophanyl residues of the subunit are similarly affected or that only one contributes to the change in emission maximum. At least two sequential steps appear to be involved in the binding of IPTG to the *lac* repressor. The first step is bimolecular and much slower than expected for a diffusion-controlled reaction. The second step is monomolecular and may be attributed to a conformational change in the protein. The circular dichroism studies showed that no major changes in the overall geometry of the peptide backbone of the repressor occurred upon binding of the inducer. The sedimentation coefficient studies indicated compactness in the protein molecule upon inducer binding. The glycerol perturbation spectra indicated that fewer aromatic residues are available to solvent in the presence of the inducer than in the protein alone or in the presence of antiinducers. It has been predicted that the repressor undergoes a conformational change upon binding to its operator and a major change for induction may be taking place upon interaction of inducer with the repressor-operator complex.

After the availability of *lac* repressor in pure form, use of it was made to isolate the operator region. The DNA having *lac* region was fragmented into smaller fragments of nearly 1000 nucleotides. In the fragmented mixture, *lac* repressor was added and after incubation for some time, it was filtered through a cellulose nitrate membrane. DNA fragments without bound *lac* repressor passed through the filter whereas fragment bound with *lac* repressor remained tightly bound with the membrane. The bound DNA was released from the cellulose nitrate filter by adding IPTG. Afterward, *lac* repressor was added and treated the fragment with deoxynuclease. The operator region gets protected from digestion by deoxynuclease after binding the *lac* repressor. Nucleotide sequence determination revealed that the repressor protected 27 nucleotides and this sequence has a *dyad* symmetry. It has been shown that this *dyad* symmetry is important for specific binding of the *lac* repressor with its operator. The symmetrical sequence of the *lac* operator region is given below:

5′ TGGAATTGTGAGCGGATAACAATT 3′

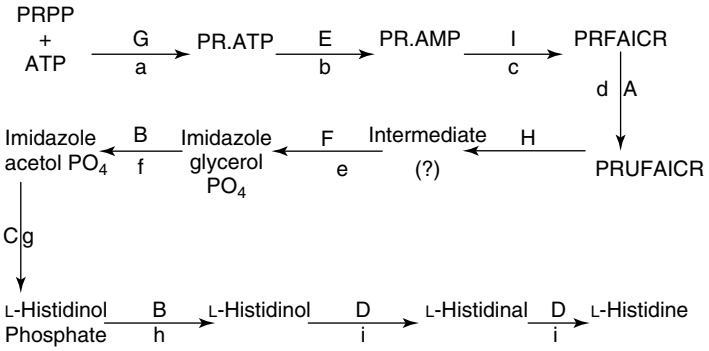
3′ ACCTTAACACTCGCCTATTGTTAA 5′

1.4 The Histidine Operon

The histidine operon is an example of enzyme repression. In *Salmonella*, most of the structural genes encoding the enzymes required for histidine biosynthesis are arranged in the same order as the sequence of chemical reactions catalyzed by respective enzymes except one or two reactions. The sequence of the genes in the histidine operon is as follows where O denotes its operator:

EIFAHBCDGO

There are nine genes that specify the structure of nine proteins involved in histidine biosynthesis. Biosynthesis of



PRPP – Phosphoribosyl pyrophosphate
PRATP – Phosphoribosyl adenosine triphosphate
PRAMP – Phosphoribosyl adenosine monophosphate
PRFAICR – Phosphoribosyl formimino amino imidazole carboxamide ribonucleotide
PRUFAICR – Phosphoribulosyl formimino amino imidazole carboxamide ribonucleotide

a - ATP phosphoribosyl transferase
b - Pyrophosphohydrolase
c - Phosphoribosyl adenosine monophosphate cyclohydrolase
d - Phosphoribosyl formimino 5-amino-imidazole-4-carboxamide ribonucleotide isomerase
e - Glutamine amido transferase
f - Imidazole glycerol-3-phosphate dehydratase
g - L-Histidinol phosphate amino transferase
h - Histidinol phosphate phosphatase
i - Histidinol dehydrogenase

Fig. 2 Histidine biosynthetic pathway. The capital letters on the arrows denote the genes encoding the enzyme catalyzing the biochemical steps.

histidine starting from phosphoribosyl pyrophosphate (PRPP) and ATP along with the genes coding for the enzymes involved has been shown in Fig. 2. Two enzymes in the pathway have been found to be bifunctional. As written above, with the exception of 1 or 2 genes, the arrangement of genes on the chromosome is related to their position in the pathway *in vivo*. This indicates that chromosome contains a remarkable amount of information not only of the sequence of the amino acids in the enzyme proteins but also about the metabolic pathway catalyzed by these enzymes.

1.5 The Tryptophan Operon

The tryptophan operon consists of five structural genes that code for the enzymes involved in the biosynthesis of tryptophan. Tryptophan biosynthesis, in addition to enzyme repression, is also controlled by feed back inhibition with tryptophan inhibiting the activity of first enzyme unique to the tryptophan biosynthetic pathway. Besides, tryptophan operon is also controlled by attenuation. The line diagram of tryptophan operon showing the structural genes, regulatory genes and other regulatory elements is shown in Fig. 3.

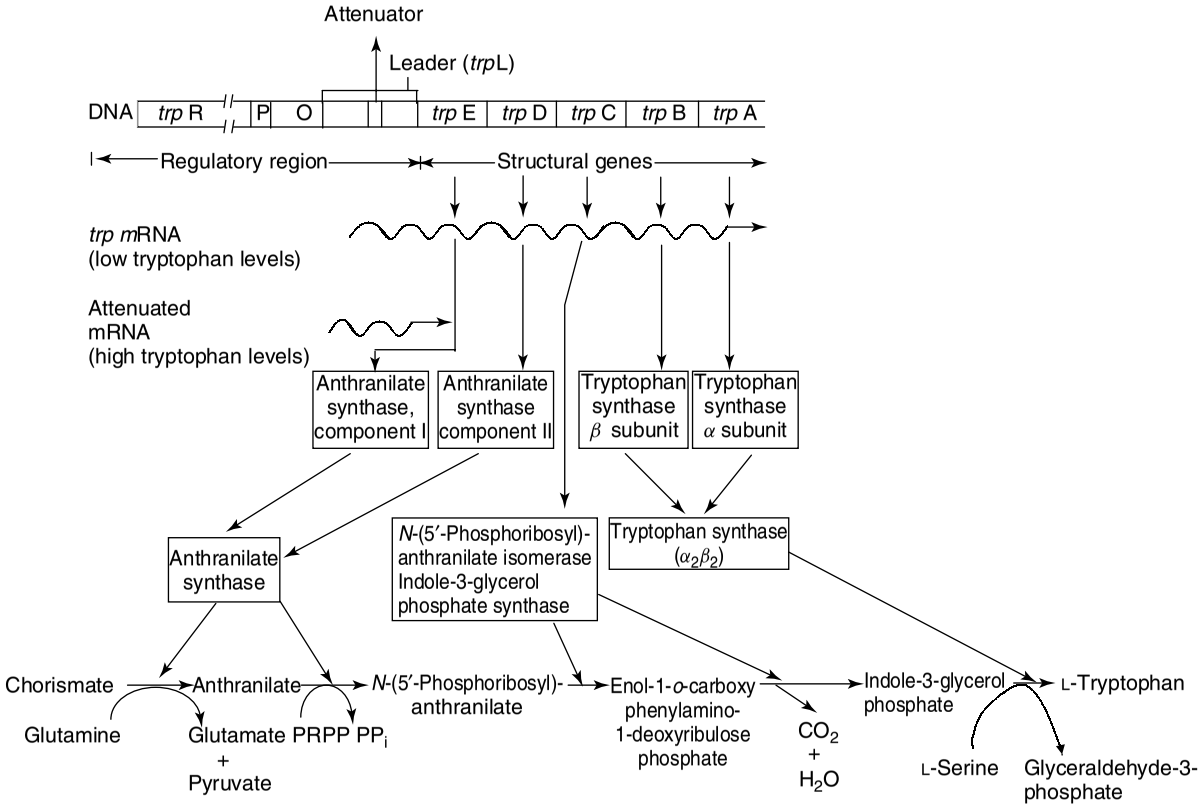


Fig. 3 Line diagram of tryptophan operon *Trp* R-regulatory gene; P, promoter; O, operator; between O and *trp* E is the leader sequence used in attenuation control. *Trp* E codes for anthranilate synthase component I and *trp* D for component II. Both components I and II on combination form active anthranilate synthase. *Trp* C codes for N-(5′-phosphoribosyl)-anthranilate isomerase Indole-3-glycerol phosphate synthase; *trp* B codes for the β subunit of tryptophan synthase and *trp* A for the α subunit of tryptophan synthase. $\alpha_2\beta_2$ complex forms active tryptophan synthase.

There is a regulatory gene called as *trp* R whose product cytoplasmic repressor is a dimeric protein having two identical subunits. Each subunit is of the molecular weight nearly 12 500 and has 107 amino acids. As in all cases of enzyme repression, in the absence of tryptophan (corepressor), cytoplasmic repressor does not bind with the operator region. In the presence of tryptophan, there is formation of cytoplasmic repressor–corepressor complex that binds with the operator region. The operator region is partially overlapped with the promoter region. The points contacted by the cytoplasmic repressor lie symmetrically and occupy the region from positions −23 to −3. The operator has the region of *dyad* symmetry, which also includes the consensus sequence of the promoter at −10. As a result, RNA polymerase is not capable of binding with the promoter region repressing the transcription of the structural genes. It is clear that the different needs of induction and repression are accomplished in almost similar manner. The difference is that the effector molecule modulates the operator binding specificity of the cytoplasmic repressor differently.

In case of tryptophan operon, deprivation of tryptophan results in approximately 70-fold increase in the frequency of initiation events at the tryptophan promoter. Even under the repressing conditions, transcription of the structural genes remains continued at a low level. In case of *lac* operon, the basal level of synthesis is only about one thousandth of the induced level. It indicates that the efficiency of repression in tryptophan operon is much lower than that seen in the *lac* operon.

1.6 Attenuation: the Leader Sequence

In the regulation of amino acid operons, generally the end product (amino acid) acts as a corepressor for repressing the transcription of the structural genes. On the basis of mechanism of enzyme repression, it was thought that regulatory gene deleted operon or operon having mutant regulatory gene, should not be under the transcriptional repression. However, in already derepressed *trp* R^- mutants, tryptophan synthesis could be stimulated by deprival of tryptophan and also by the internal deletion of the region between the operator and first structural gene. On the basis of these findings, a second mechanism of regulation involving variable, premature termination of transcription in this region was elucidated. This process is called as *attenuation*. On analysis of the sequence of early mRNA of the tryptophan operon, a part of this sequence was found to code for a short leader peptide. Variation in the translation of leader peptide is dependent on the supply of tryptophan. Tryptophan influences the frequency of termination of transcription at the attenuator site, which lies still further ahead.

Attenuation controls the ability of RNA polymerase to read through an attenuator, an intrinsic terminator located at the beginning of a transcription unit. The common feature of attenuator systems from different operons is that some external event controls the formation of the hairpin needed for intrinsic termination. If the hairpin is allowed to form, termination prevents RNA polymerase to transcribe the structural genes. If the hairpin is prevented from forming, RNA polymerase elongates through the terminator, and the structural genes are expressed. Control by attenuation requires a precise timing of events that control termination. Translation of the leader peptide must occur at the same time when RNA polymerase approaches the terminator site. The RNA polymerase remains paused till translation

of leader peptide on the ribosome occurs. Thereafter, the RNA polymerase is released and moves toward the attenuation site. By providing a mechanism to sense the inadequacy of the supply of Trp-tRNA, attenuation responds directly to the need of the cell for tryptophan in protein biosynthesis and uses attenuation as a control mechanism.

In the tryptophan operon, the attenuator lies within the transcribed leader sequence of 162 nucleotides that precedes the initiation codon of *trp* E. It has *rho* independent termination site and is a barrier for transcription. A short G C rich palindrome sequence is followed by eight successive U residues. RNA polymerase terminates at this site producing only a 140 nucleotide mRNA. The leader region sequence contains ribosome binding site and has an open reading frame for coding a peptide of 14 amino acids called as leader peptide. The leader peptide is unstable. The sequence of the leader peptide is as follows:

Met-Lys-Ala-Ile-Phe-Val-Leu-Lys-

Gly-Trp-Trp-Arg-Thr-Ser

As is clear from the sequence of the leader peptide that out of 14 amino acid residues, two are tryptophanyl residues. Tryptophan is considered to be a rare amino acid in proteins; therefore its abundance in leader peptide has some significance. When the amount of tryptophan in the cell is deficient, biosynthesis of the leader peptide on the ribosome gets stopped when it reaches the *trp* codons. The sequence of the mRNA suggests that this ribosome stalling may in turn influence termination at the attenuator. Pairing of the regions generates the hairpin that precedes the oligo U sequence, a termination signal for transcription. The position of ribosome can determine which structure is formed. When tryptophan is deficient in the cell, ribosomes stall at the trp codons, which are part of region 1. This region 1 gets sequestered within the ribosome and cannot base-pair with region 2. Under the conditions, region 2 will base-pair with region 3 compelling region 4 to remain in a single-stranded form. In the absence of terminator hairpin, RNA polymerase continues transcription after the attenuator. When tryptophan is present in the cell, biosynthesis of the leader peptide occurs through the *trp* codons. Synthesis remains continued along the leader section of the mRNA to the UGA codon which lies between regions 1 and 2. Under the conditions, ribosomes extend over region 2 and prevent it from base-pairing with region 3. Now, region 3 remains available to base-pair with region 4 generating a termination hairpin. This results in the termination of transcription at the attenuator (Fig. 4).

Regulation by attenuation mechanism has been found in many amino acid operons of *E. coli*, for example, *His*, *Phe*, *Leu*, *Thr*, *ilv*.

1.7 Positive and Negative Control

Positive and negative control systems are distinguished on the basis of mode of action of the cytoplasmic repressor. Genes under the negative control are unable to get transcribed in the presence of the product of the regulatory gene (cytoplasmic repressor) but are transcribed in the absence of cytoplasmic repressor. It indicates that cytoplasmic repressor switches off the transcription. The cytoplasmic repressor either binds to DNA to prevent RNA polymerase from initiating transcription or binds to mRNA to prevent a ribosome from

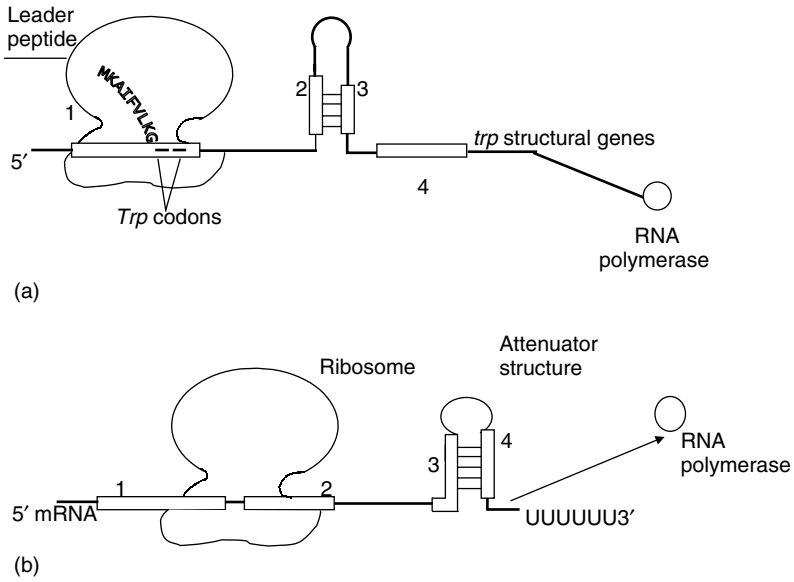

Fig. 4 Ribosomal stalling. (a) When tryptophan levels are low, biosynthesis of the leader peptide on the ribosome gets paused at the *trp* codons in region 1. The region 1 sequence gets sequestered within the ribosome and cannot base-pair with region 2. Therefore, region 2 base-pairs with region 3, compelling region 4 to remain in a single-stranded form. (b) When tryptophan levels are high, biosynthesis of leader peptide occurs through *trp* codons. Synthesis remains continued along the leader section of the mRNA to the UGA codon present between regions 1 and 2. The ribosome extends over region 2 and prevents it from base-pairing with region 3. Now region 3 base-pairs with region 4 generating a termination hairpin.

initiating translation. In fact, negative control provides a fail-safe mechanism. The *lac* operon described above is an example of negative control.

The tryptophan operon described above is another example of negative control. The level of tryptophan in the cell regulates both the activity and synthesis of the tryptophan synthesizing enzymes. Tryptophan inhibits the catalytic activity of the first enzyme of the pathway. Thus, tryptophan inhibits the synthesis of further molecules of the amino acid by inhibiting the beginning of the pathway. Tryptophan also acts as corepressor that activates the product of *trp* R gene. When tryptophan is present, tryptophan operon gets repressed by binding cytoplasmic repressor (product of *trp* R gene)-tryptophan complex to the operator region.

Genes under the positive control are expressed only when an active regulatory protein is present. The regulatory protein acts to switch on transcription and is thus an activator protein. Such activator proteins are also called as *positive control factors*. The regulatory protein interacts with DNA and with RNA polymerase to assist the initiation. A positive control factor that responds to a small molecule is called an *activator*. However, the activator alone cannot bind to the operon. It requires another molecule to be bound to the activator protein, which increases the

DNA-binding ability. An example is cyclic AMP activated cyclic AMP receptor protein (CRP) which activates arabinose operon. You will find in the arabinose operon, that it is an example of both negative and positive control.

1.8 The Arabinose Operon (*Ara* Operon)

The arabinose operon in *E. coli* consists of three structural genes that code for the enzymes involved in the utilization of arabinose. *E. coli* can utilize arabinose as a carbon source. This operon is an example of both positive and negative control. A line diagram of *ara* operon showing structural genes, regulatory gene, and regulatory elements is shown in Fig. 5. The *ara* C is the regulatory gene whose product is called Ara C protein. Biosynthesis of Ara C protein is self-regulatory. Ara C protein regulates its own biosynthesis after binding with *ara* O_1 operator. It represses its *ara* C gene transcription. Generally, about 40 copies of Ara C protein are present in the cell. The Ara C protein acts as positive and negative regulator for the transcription of structural genes, *ara* B, *ara* A, and *ara* D which code for L-ribulose kinase, L-arabinose isomerase and L-ribulose-5-phosphate epimerase, respectively. Some regulatory DNA sequences exert their effect from a distance. These sequences are not always contiguous with promoters. These distant DNA sequences come close together by DNA looping mediated by specific protein–protein and protein-DNA interactions.

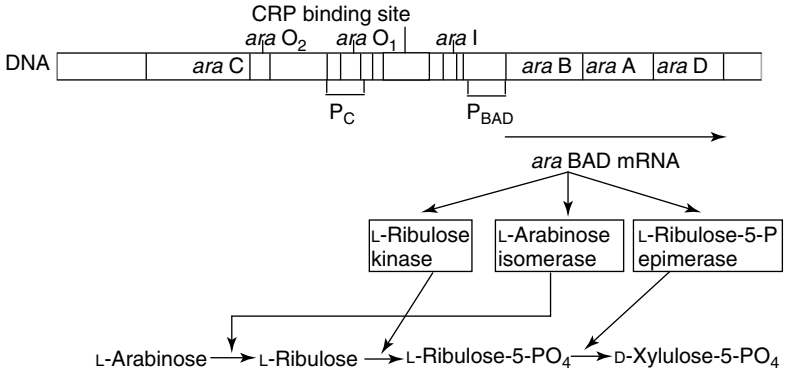

Fig. 5 Line diagram of arabinose operon: *ara* C, regulatory gene; *ara* O_2, *ara* O_1 and *ara* I, regulatory elements where *ara* C gene product may bind; Pc, promoter for *ara* C gene; P_{BAD}, promoter for BAD genes; *ara* B, *ara* A and *ara* D, structural genes for L-ribulose kinase, L-arabinose isomerase, and L-ribulose-5-phosphate epimerase, respectively. Ara C protein regulates its own synthesis after binding on *ara* O_1 resulting in the repression of transcription of *ara* C gene. Ara C protein acts as positive as well as negative regulator for *ara* BAD genes. If arabinose is absent and glucose present, ara C protein binds with *ara* O_2 as well as *ara* I forming a DNA loop and there is repression of *ara* BAD genes. If arabinose is present, cAMP–CRP becomes abundant and binds on the site adjacent to the *ara* I site (CRP binding site). Arabinose also binds to the ara C protein altering its conformation, DNA loop is opened and ara C protein bound on *ara* I acts as activator for transcription of *ara* BAD genes.

When glucose is present and arabinose is not present, Ara C protein binds to *ara* O_2 and *ara* I both, forming a DNA loop of about 210 nucleotides. In this condition, there is repression of the transcription of the structural genes. If glucose is not present and arabinose present, cyclic AMP and CRP become abundant and complex of cyclic AMP and CRP binds to its site adjacent to *ara* I. Arabinose binds with Ara C protein changing its conformation. Now after the binding of arabinose to Ara C protein, DNA loop is opened and Ara C protein bound on *ara* I acts as activator and in concurrence with cyclic AMP–CRP complex, induce transcription of the structural genes. If arabinose and glucose both are present, then also there is repression of transcription, perhaps due to catabolite repression concentration of cyclic AMP is lowered.

1.9 Catabolite Repression

Glucose is the most easily utilizable sugar for energy purpose, therefore, is preferred by *E. coli* as a carbon source. If *E. coli* cells are grown in a medium containing both glucose and lactose, there is no induction of *lac* operon. After utilization of glucose, cells start utilizing lactose and now there is induction of *lac* operon for the biosynthesis of β-galactosidase. In the presence of glucose, the lactose operon is not induced. The inhibitory molecule is not glucose itself but some unknown catabolite derived from glucose which acts by preventing expression of several operons, including lactose, galactose and arabinose operons. This effect is called as *catabolite repression*. It represents a general coordinating system that exercises a preference for glucose by inhibiting the expression of the operons that code for the enzymes of alternative metabolic pathways.

Catabolite repression does not work by preventing the entry of sugars but by inhibition of transcription. In the presence of glucose, there is much decrease in the concentration of cyclic AMP in the cell. The unknown catabolite derived from glucose stimulates phosphodiesterase thereby, converts cyclic AMP into 5′ AMP. There is no decrease in the activity of adenylyl cyclase enzyme responsible for converting ATP into cyclic AMP. Cyclic AMP binds with CRP and the complex stimulates transcription of catabolite sensitive operons. CRP is also called as *catabolite gene activator protein* (CAP). It is a positive control factor whose presence is essential to initiate transcription at CAP dependent promoters. CRP without cyclic AMP is unable to stimulate transcription. Cyclic AMP–CRP binding to DNA changes its structure in some way that assists RNA polymerase to bind.

1.10 Cyclic AMP Receptor Protein

Cyclic AMP plays an important role in controlling the catabolic activity of both prokaryotic and eukaryotic cells. In prokaryotes, cyclic AMP modulates transcription through CRP, also known as CAP, whereas, in eukaryotes, cyclic AMP modulates the enzyme activity by covalent modulation through cyclic AMP dependent protein kinases.

CRP does not bind to DNA without prior binding of cyclic AMP. Among the genes that are activated in bacteria in response to an increase in cyclic AMP are that encode the enzymes for the catabolism of lactose, arabinose, galactose, maltose, and so on. Presence of cyclic AMP is necessary for activation of transcription in bacteria.

This has been demonstrated by mutating the gene coding for adenylyl cyclase (*cya*$^{-}$) which converts ATP into cyclic AMP. If cyclic AMP is added externally in such system, then there is activation of the transcription. Promoters of the operons whose expression depends on cyclic AMP and CRP contain specific sites for binding cyclic AMP–CRP complex. *In vitro* transcription of DNA fragments containing cyclic AMP–CRP dependent promoters is also activated by cyclic AMP–CRP. In some cases, mutant promoters have been isolated at which cyclic AMP–CRP is unable to bind. At these promoters, cyclic AMP–CRP fails to activate transcription both in intact cells and *in vitro*.

It has been found that one CRP dimer (after binding two cyclic AMP molecules) binds at the specific site in the operon whose transcription is activated by cyclic AMP–CRP. With the help of CRP protection experiments against chewing by deoxynuclease, it has been found that approximately 25 bp are protected. The bases protected by cyclic AMP–CRP from chemical attack and the mutations that prevent CRP binding are located within these sequences. The experiments indicated that CRP makes major contacts in two successive grooves of the DNA. The most-conserved sequence that binds CRP is 5′TGTGA3′. All the evidences indicate that 5′TGTGA3′ sequence is critical for CRP binding. At the *gal* and *lac* sites, point mutations known to prevent stable CRP binding are located in this sequence. At the *ara* site, deletion experiments showed the importance of this sequence for CRP binding. There is an another sequence 6 bp downstream of the TGTGA motif and has inverted repeat. Although in many cases, it is not exactly inverted repeat sequence. This second motif irrespective of the symmetry of the sequence has also been shown to be required for efficient CRP binding. Many types of experiments indicated that the two subunits of CRP recognize two zones of sequences separated by 6 bp. As written above, one of these zones contains the sequence 5′TGTGA3′. The other stretch contains either a symmetrically arranged second version of this sequence or another type of sequence. However, affinity of CRP for DNA appears to be more when 6-bp downstream sequence of 5′TGTGA3′ is symmetrical compared to when it is not symmetrical. The distance between the transcription start point and the CRP binding site is different at different promoters. At some promoters like those for *ara* operon and *mal* operon, an additional protein, the Ara C protein or the Mal T protein is also required for activation of the transcription. These activator proteins also bind to the promoter. In some cases (for example *lac*, *cat*), two CRP binding sites have been found. The secondary sites bind CRP less tightly. It is considered that these secondary sites might help in the search of CRP for the primary sites.

Although, the main function of CRP is to activate transcription, in some cases, binding of CRP has been shown to repress transcription. At the *gal* promoter, there are two promoters, P1 and P2. When CRP binds at the P1, it activates transcription. However, when CRP binds at P2, it represses transcription. This is due to the fact that at P2, CRP binds near the −35 region blocking the binding of RNA polymerase at the P2 promoter. CRP also acts as a repressor of transcription of its own promoter *in vitro*. CRP also inhibits transcription of the gene for the major outer membrane protein, Omp A, again by binding near the −35 region of the promoter.

CRP is a dimeric protein having two identical subunits, each containing 210

amino acids. Complete amino acids sequence is known as deduced from the nucleotide sequence of the gene. Equilibrium dialysis studies indicated that two molecules of cyclic AMP could bind per CRP dimer. CRP has a two-domain structure as indicated by the resolution crystal structure of CRP complexed with cyclic AMP. A large amino terminal domain extending from residue 1 to 135 is separated by a cleft from a smaller carboxy terminal domain that extends from residue 136 to 210. The amino terminal domain of each subunit contains one cyclic AMP molecule buried in the interior of the protein. Residues from both subunits are involved in the binding of cyclic AMP. The 6-amino group of the adenine ring in cyclic AMP interacts with Thr^{127} on one subunit and Ser^{128} on the other subunit.

Amino terminal domain of CRP in the region of 30 to 89 residue, exhibits sequence homology with the regulatory subunit of the protein kinase of eukaryotes. Regulatory subunit of protein kinase also has two cyclic AMP binding sites.

The carboxyl terminal domain of each CRP subunit consists of three α-helices connected by short β-sheet structures. In each subunit, one of the α-helices protrudes from the surface of the CRP dimer. These two α-helices are considered to be involved in DNA binding. The other DNA binding proteins like Cro and cI proteins also have α-helices but in the amino terminal region. It has been shown that all the DNA-binding proteins have helix turn helix domain essential for interactions with DNA. However, *E. coli* fnr protein, which is essential for anaerobic respiratory metabolism, also has helix turn helix domain in carboxyl terminal region. Additional homology is also found in the amino terminal regions of the two proteins. Although fnr protein does not bind cyclic AMP, it has a somewhat similar function as CRP. The fnr protein is a pleiotropic activator for a series of genes that are turned on under limiting aerobic conditions. The sequence comparison indicated that *fnr* gene might have derived by duplication either from the *CRP* gene itself or from a common ancestor.

Interactions between RNA polymerase and promoters may be described as a two-step event. First, the enzyme binds to the promoter to form a closed complex. This binding step is reversible and is characterized by an association constant, K_B. In the second step, the closed complex isomerizes to give rise an open complex. This isomerization includes a localized unwinding of the DNA over a distance of approximately 12 bp near the transcription start is generally irreversible and the corresponding rate constant, K_f, is slow. Strong promoters have high values of both K_B and K_f, whereas, weak promoters have low values for both the constants. Addition of cyclic AMP and CRP has two effects on *lac* promoter. First, it enhances the rate of open complex formation by increasing the value of K_B without affecting the value of K_f. Second, the presence of cyclic AMP–CRP also increases the binding of RNA polymerase on P1 promoter. This increased binding of RNA polymerase on P1 is due to inhibition of RNA polymerase binding on other secondary sites in the presence of cyclic AMP–CRP. The structure of the CRP-DNA complex is interesting. The DNA has a bend. Proteins may distort the double helical structure of DNA when they bind and several regulatory proteins induce a bend in the axis. Therefore, there is a dramatic change in the organization of the DNA double helix after the binding of CRP.

1.11
Guanosine-5′-Diphosphate, 3′-Diphosphate

The *rel* A gene required for the synthesis of guanosine-5′-diphosphate, 3′-diphosphate (ppGpp) has been shown to enhance the transcription of *lac* Z gene and *glg* genes (genes coding for glycogen biosynthetic enzymes). There are indications that ppGpp interacts directly with RNA polymerase to directly alter the transcription of various genes. A small protein has been shown to mediate the effect of ppGpp on *lac* Z gene under certain conditions. Nitrogen regulatory proteins C and A (Ntr C and Ntr A) are also shown to activate *gln* promoter. The *ntr* C and *ntr* A genes encode a specific DNA-binding protein and an alternate sigma factor for RNA polymerase, respectively. However, Ntr C and Ntr A did not increase the synthesis of glycogen biosynthetic enzymes.

2
Regulation of Gene Expression in Eukaryotes

Compared to prokaryotes, eukaryotes have more complex regulatory mechanism of transcription. In addition, RNA splicing also plays important role in the regulation of gene expression. Besides, activation of gene structure, polyadenylation of mRNA, capping of mRNA, transport of mRNA to cytoplasm, translation of mRNA are the potent control points in the process of regulation of gene expression. Figure 6 shows five potential control points for regulation of gene expression in eukaryotes. The most important way to control gene expression is by regulating the initiation of transcription (interaction of RNA polymerase with the promoter region). The regulation of initiation of transcription may be demonstrated by a technique called as *run off transcription*. In this technique, nuclei are isolated from the cells and are incubated with radiolabeled nucleoside triphosphates. Under suitable conditions, unfinished transcripts are completed, but no new transcripts are synthesized. Therefore, the RNA labeled by this method is derived from genes that have started transcription at the time of isolation of the nuclei. The labeled RNA is used to probe DNA from a clone of the genes under investigation. The absence of any hybridization between the labeled RNA and the cloned DNA indicates that the DNA is not transcribed in the tissue. This technique has been used to examine

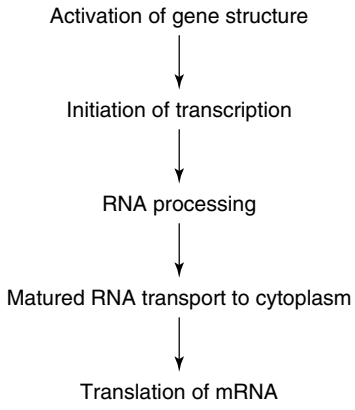

Fig. 6 Regulation of gene expression. Gene regulation may take place in a gene-specific way at any of the several sequential steps. However, there are five potential control steps.

a number of genes. The absence of gene expression does, indeed, result from the absence of transcription.

Now a days, *DNA microarray technology*, more commonly known as *''gene chip technology''* is also being used to examine the presence of complementary sequences. In fact, microarray technology is a genetic revolution of today and may be compared with the microprocessors to the computer revolution 25 years ago. The microarray technology has changed the job of screening the genetic information into an automatic routine that exploits the tendency for the molecule that carries the template for synthesizing mRNA, protein, to bind to the DNA that produces it. The microarrays contain thousands of probes, each imbued with a different nucleic acid from known and unknown genes to bind with mRNA. The resulting bonded molecules fluoresce under different colors of laser light showing which complementary sequence is present. The microarrays can measure the incidence of genes and their expression. After the human genome sequence availability, importance of single nucleotide polymorphism (SNP) has also been appreciated. The SNP is minor variations in DNA that define differences among people, predispose a person to disease, and influence a patient's response to a drug. With the genetic makeup of human broadly known, it is now possible to build microarrays that can target individual SNP variations as well as making deeper comparisons across the genome. All these studies may help in finding the roots of many diseases. Nowadays, specific software are also available to design microarrays with much number of probes.

Real-time Polymerase Chain Reaction (RT PCR) has also been used to measure the level of gene expression. It is a highly sensitive and convenient technology and its approaches are a natural complement of transcriptone analysis, either when tuning of array results is necessary or when array sensitivity limit is reached for low-level transcripts of interest. In RT PCR, sensitive quantification of PCR products relies on detection of a fluorescent signal proportional to the amount of product. PCR products can be measured in real time by the use of a double-stranded DNA-binding dye which does not bind with single-stranded DNA, or labeled oligonucleotides that specifically bind to the PCR products.

Cells of multicellular organisms are genetically homogeneous but structurally and functionally heterogeneous because of differential expression of genes. Many of these differences in gene expression occur during development and are retained through mitosis. Stable alterations of this type are called to be *epigenetic*, because they are heritable in the short term but do not involve mutations of the DNA itself. Researches have focused on two molecular mechanisms that mediate epigenetic phenomena namely DNA methylation and histone modifications. It has been shown that epigenetic effects by means of DNA methylation have an important role in development but can also arise stochastically as animal age. Identification of proteins that mediate these effects has helped in elucidating the epigenetic effects. When it gets perturbed, diseases may occur. External factors on epigenetic processes are found in the diet on long-term diseases like cancer. It has been indicated that epigenetic mechanisms allow an organism to respond to the environment through changes in gene expression.

There are many genes that are transcribed in one tissue or organ but not in others. In fact, this explains the cell differentiation in eukaryotes. Some genes

are expressed under the influence of certain signaling agents such as substrates of specific enzymes, hormones, regulatory nucleotides, and so on. Expression under the influence of certain signaling agents has also been considered as *induction*. Although the phenomena of induction is not that much prominent in eukaryotes as in prokaryotes. In eukaryotes, it takes more time and the amount stimulated is only about 10 to 20 times in contrast to bacteria where stimulation to the extent of thousands times has been found as a result of induction. In eukaryotes, monocistronic mRNA are found in contrast to polycistronic RNAs in prokaryotes, therefore, coordinate induction has also not been reported in eukaryotes. Longtime back, a model named as Britten Davidson model was proposed for explaining induction phenomena in eukaryotic genes. According to this model, eukaryotic genome contains a large number of sensor sites that recognize specific molecular signaling agents such as hormones, substrates of specific enzymes, and so on. Each sensor site is adjacent to an **integrator gene**. When sensor site is activated after binding of a signaling agent, the integrator gene is transcribed to form its complementary RNA called as *activator RNA*. The activator RNA in turn is recognized by one or more receptor sites located elsewhere in the genome. The receptor sites may be on the same or some other chromosome. When activator RNA binds on the receptor site, an adjacent structural gene is transcribed (Fig. 7).

Although, the phenomena of coordinate expression in eukaryotes was considered to be nonexistent owing to monocistronic mRNAs, using DNA microarrays, global expression analysis showed highly coordinate expression of genes functioning in common processes in eukaryotes. It has been called as "*syn-expression*." The syn-expression in eukaryotes has been considered comparable to operons in prokaryotes. It is also proposed that it may be a key determinant facilitating evolutionary change leading to animal diversity. Using DNA microarrays, simultaneous monitoring of thousands of transcripts is possible. These studies gave global insights into gene expression. The expression data revealed a high-degree of order in the genetic program, a tight coordination of the expression of groups of genes functioning in a common process.

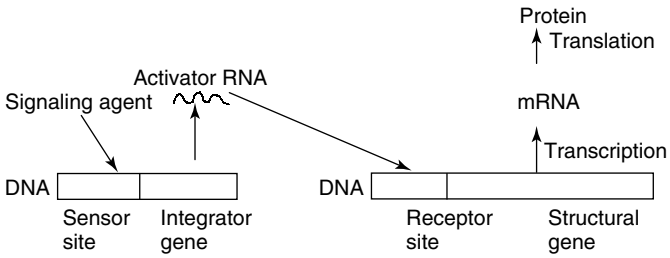

Fig. 7 Britten Davidson model of gene regulation: when a signaling agent such as hormone binds on sensor site, there is transcription of integrator gene forming its complementary RNA called as activator RNA. The activator RNA is recognized by the receptor site located elsewhere in the genome. When activator RNA binds on the receptor site, adjacent structural gene is transcribed and afterward translated.

Frenster while working with mammalian cells infected with SV40 virus suggested a derepressor model for gene regulation in eukaryotes. On the basis of experimental data indicating the ability of exogenous DNA or RNA to derepress specific loci on the host cellular genome, the model suggested a close relationship to the normal mechanisms of gene regulation in animal cells, which may be subverted to allow reexpression of otherwise repressed embryonic information. The derepression model accounts for selective gene transcription that is locus and strand specific but does not discuss gene–gene interactions. Afterward, Frenster proposed a Mated Model of gene regulation in eukaryotes.

According to the Mated Model, a derepressor RNA (dRNA) binds to anticoding strand of operator locus permitting transcription of operator and structural gene loci. The derepressor RNA of an operon is complementary in base sequences to its operator portion of the direct transcription product. Afterward, direct transcription product gets split into mRNA and operator RNA (oRNA). The cleavage may occur directly or after formation of heterometric duplex RNA by base-pairing of derepressor RNA with the operator portion. Thereafter, derepressor RNA is selectively removed from the operator locus providing feedback inhibition of transcription of the operon. With consumption of mRNA and with degradation of operator DNA, derepressor RNA is released from the duplex providing positive feedback derepression of transcription of the operon. Different structural genes may share operators with common base sequences, and thereby are equally sensitive to given species of derepressor RNA both during gene transcription and during its selective inhibition (Fig. 8).

In eukaryotes, normally cell division is highly regulated with the help of growth factors that cause the cells to undergo cell division and in some cases, cell differentiation. Some growth factors are specific for certain type of cells due to specific receptors present at the surface of the cell. Some growth factors are general rather than specific in their effects. Some growth factors controlling the cell division are epidermal growth factor, nerve growth factor, platelet derived growth factor, fibroblast growth factor, lymphokines, and so on. In fact, sometimes due to failure of control of the cell division by growth factors, there may be uncontrolled cell division causing tumors.

In prokaroyotes, negative control of transcription plays an important role (fail safe mechanism). However, in eukaryotes, positive control plays a more important role. It is due to the simple reason that in a large genome, it is more efficient. If so many genes have to be negatively controlled, each cell would have to synthesize the same number of different repressors in sufficient amount to permit specific binding of each. Besides, nonspecific DNA binding of regulatory proteins (repressors) is also an important problem in much larger genomes of higher eukaryotes. The chance of specific-binding sequence to be present randomly at inappropriate sites also increases with genome size.

2.1 Transcriptionally Active Chromatin

The major part of the eukaryotic genome is sequestered in the nucleus where it is surrounded by a nuclear membrane, safeguarding it from exposure to the cytoplasm. Transcription of the genes also occurs within the nucleus. However,

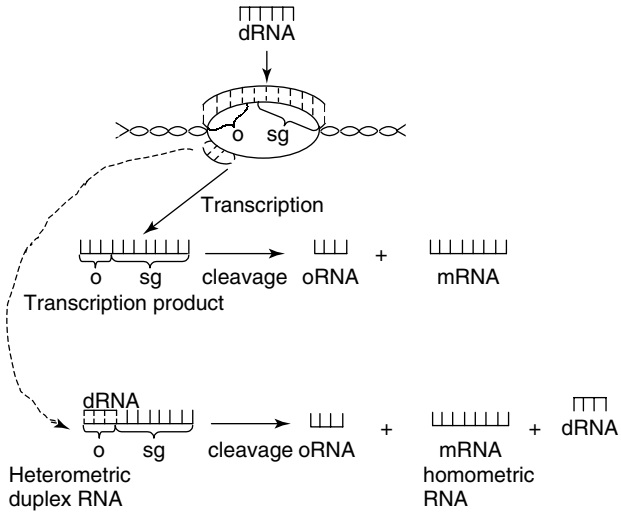

Fig. 8 Mated model for gene regulation: o, operator; sg, structural gene; dRNA, derepressor RNA. Derepressor RNA (dRNA) binds to anticoding strand of operator locus permitting transcription of operator and structural gene loci. The transcription product gets split into mRNA and operator RNA (oRNA). The cleavage may occur directly or after formation of heterometric duplex RNA.

translation occurs mainly in the cytoplasm. Therefore, coupling of transcription and translation cannot occur. The chromosomes of eukaryotes are more complex than of the bacteria. Each eukaryotic chromosome contains a double helix DNA molecule that may be more than twenty times larger than that of bacterial chromosomes. The DNA is tightly complexed with histone proteins that are considered to have structural and protective functions. Additionally, there are some loosely bound nonhistone proteins. These are mostly present in smaller quantities than histones. The functions of nonhistone proteins are not exactly known, these may have role(s) in transcription and/or in replication. Mitochondrial and chloroplast DNAs are small double-stranded molecules. Plant mitochondrial DNA is larger than that of animals. All plants seem to have similarly sized chloroplast DNA. Mitochondrial and chloroplast DNAs resemble bacterial DNA and unlike eukaryotic nuclear DNA are not associated with histones.

It has been seen that chromosomal regions that have been activated for transcription are more sensitive to DNase degradation indicating lesser protection by histones. It has also been found that actively transcribed regions have sequences that have high sensitivity to DNase, and these have been called as *hypersensitive sites*. These hypersensitive sites are generally not more than 200-bp long and are generally found with in the 1000 bp flanking the 5′ ends of transcribed genes. In some cases, these hypersensitive sites are found farther from the 5′ end, near the 3′ end or within the gene itself. Many hypersensitive sites have

been found to be the binding sites for regulatory proteins.

Telomeres are the specialized structures at the ends of linear eukaryotic chromosomes. They generally have many tandem copies of a short oligonucleotide sequence, T_aG_b in one strand and C_bA_a in the complementary strand where a and b are 1 to 4. The structure of telomere poses a biological problem. DNA replication requires a primer but in linear DNA molecules it is impossible to synthesize an RNA primer starting at the end nucleotide. The problem is solved by telomerase, an enzyme resembling reverse transcriptase. It adds telomeres to chromosome ends. Telomerase has both RNA and protein in its structure. The RNA part is about 150 nucleotides long and has about 1.5 copies of C_bA_a telomere repeat. This telomere repeat part acts as a template for synthesis of the T_aG_b strand of the telomere. Telomerase like reverse transcriptase synthesizes only a segment of DNA that is complementary to an internal RNA molecule.

The DNA in transcriptionally active chromatin has been found to be less methylated. Besides, nucleosomes have also not been found in transcriptionally active regions (at least in some cases). Chromatin has been classified into two groups – *heterochromatin*, a highly condensed chromatin which is transcriptionally inert, and *euchromatin*, a loosely packed chromatin and transcriptionally active.

2.2 Regulation of Gene Expression at the Initiation of Transcription

Regulation of gene expression at the initiation stage of transcription (binding of RNA polymerase onto the promoter) has been evidenced. At present, there is no evidence for control of gene expression at the subsequent stages of transcription. Three RNA polymerases have been found in eukaryotic cells for biosynthesis of different classes of RNAs. Biosynthesis of HnRNA takes place in the presence of RNA polymerase II. Initiation of transcription by RNA polymerase II is regulated by a series of DNA elements that may be divided into the core promoter element consisting of TATA box, the transcription initiation site and the upstream activating sequences (UAS). The UAS are usually found upstream of the core promoter sequence but in some cases, have been found downstream of the transcription start site (Fig. 9). A specific protein gets bound on each UAS resulting in a positive or negative effect on the core promoter activity. TATA box is found generally 25-bp upstream from the transcription initiation site. Although TATA box is common in eukaryotic genes, few genes have been shown to get expressed without TATA box. Besides, TATA box, another sequence called as CAAT box has been found at the −75 position from the initiation site. It functions in either orientation and plays an important role in increasing the promoter strength. It has the consensus sequence GGCAATCT. A GC box at −90 position from the initiation site has also been found. It occurs in either orientation and is a common component of the promoters of house-keeping genes. The GC box has the consensus sequence GGGCCGGG.

Transcription factor D for RNA polymerase II (TFIID) has been shown to play an important role in the initiation of transcription by binding on TATA box sequences. After binding of TFIID, it facilitates the binding of the RNA polymerase II on to the promoter. The assembly of an initiation complex and RNA polymerase

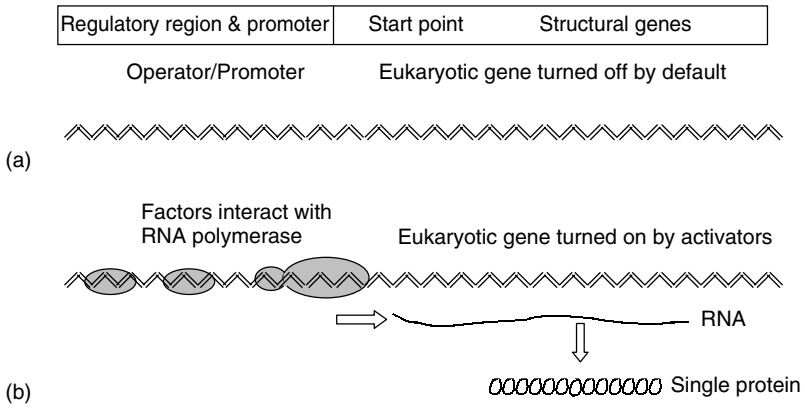

Fig. 9 Regulation of eukaryotic gene expression at transcriptional level. Eukaryotic control is often positive: trans-acting factors bind to cis-acting sites in order for RNA polymerase to initiate transcription at the promoter. (a) Transcription gets turned off by default (if proper initiation factors are not bound in the regulatory region). (b) Transcription gets turned on after the binding of initiation factors on the regulatory region, after which RNA polymerase binds on the promoter region.

at the promoter is a complex process that requires participation of many other initiation factors. TFIID has two components, TATA box binding protein (TBP) and another protein called as TBP associated factor (TAF). TBP associated factor is also important for regulating the transcription. TBP, also called as the ''commitment factor,'' binds to DNA in the minor groove. The inner surface of TBP binds to DNA and the outer surface is available to extend contacts to other proteins. The DNA binding sites consist of sequences that are conserved between species. The variable N-terminal tail is exposed to interact with other proteins. TBP is the only transcription factor that makes contacts with the specific sequences in DNA. The activity of TFIID has also been shown to be regulated by inhibitory proteins that interact with TBP. Such inhibitory proteins may serve an important regulatory role by keeping genes that have been removed from inactive chromatin in a repressed but rapidly inducible state.

There are other factors too that play an important role in the regulation of initiation of transcription. Transcription Factor II A (TFIIA) joins the initiation complex after TFIID. It has two subunits in yeast and three in mammals. After joining of TFIIA, TFIID becomes able to protect a region extending further upstream. Addition of Transcription Factor II B (TFIIB) gives further protection to the region of the template in the vicinity of the start point from -1 to $+10$ bp. The TFIIF is a dimeric protein. The larger subunit has ATP-dependent DNA helicase activity that could be involved in opening the DNA during initiation. The smaller subunit has been found to be equivalent of sigma factor of *E. coli*. The TFIIF brings RNA polymerase II to the assembling transcription complex and provides the means for its binding. Interaction with TFIIB may be important when TFIIF joins the complex. Polymerase binding extends the sites that are protected downstream to $+15$ on the template strand and $+20$

on the nontemplate strand. TFIIE binds at the upstream boundary. Two more factors, TFIIH and TFIIJ also join the complex after TFIIE. TFIIH has kinase activity that may phosphorylate the CTD (carboxy terminal domain) tail of RNA polymerase II, which consists of multiple repeats of the consensus sequence, Tyr-Ser-Pro-Thr-Ser-Pro-Ser. This sequence is unique to RNA polymerase II. Phosphorylation of the tail (at seryl or threonyl residue) is required to release the enzyme from the transcription factors, so that it can leave promoter region to start elongation. The TATA box determines the location of the start point. The general initiation process of transcription is the same as in bacteria. The enzyme RNA polymerase generates a closed complex and afterward is converted into an open complex where DNA strands get separated. In the process of open-complex formation, there is removal of TFIIE.

The CAAT box is recognized by the proteins of the CTF (CCAAT-binding transcription factor) family which are generated by the alternative splicing from a single gene. The CP1 factor binds to the CAAT boxes of α-globin and CP2 binds CAAT box in a β-fibrinogen gene. Other proteins also bind CAAT boxes. The ACF (albumin CCAAT factor) protein binds CAAT in the albumin promoter. The CAAT box may also be a regulatory point. In embryonic tissues, a protein called CDP (CAAT displacement protein) binds to the CAAT boxes preventing the transcription factor from recognizing them. In testes, the promoter is bound by transcription factor at the TATA box, CAAT box and the octamer sequences. In embryonic tissue, exclusion of CAAT binding factor from the promoter prevents a transcription complex being assembled. This behavior is analogous to the effect of bacterial repressor.

The GC box is recognized by the factor SP1, a monomeric protein which makes contacts on one strand of the DNA over a −20 bp binding site including GC box. In SV40 promoter, the multiple boxes between −70 and −110 all bind this factor protecting the whole region. However, in thymidine kinase promoter, SP1 interacts with a factor at the CAAT box on one side and with TFIID bound at the TATA box on the other side.

Additional regulatory sequence elements are enhancers in higher eukaryotes and UAS in yeast. For enhancer, the location and orientation of sequences relative to transcription start site are relatively unimportant. The enhancers exert their regulatory effects even when moved experimentally and they may naturally occur thousands of base pairs away from the gene being regulated. The enhancers have no promoter activity of their own but may stimulate transcription over considerable distances. The enhancers may be involved in regulation of gene expression during the development of the organism like the immunoglobulin enhancer which only functions in B-lymphocytes.

Regulatory role of enhancer activity has been found in the transcription of genes responsive to steroid hormones. The steroid gets bound on to a soluble protein, which in turn binds the enhancers for the steroid responsive genes. Transcriptional activation is also accompanied by the decondensation of the chromatin in the regions containing the genes which is evident by the fact that the region becomes more sensitive to DNase I digestion and subsequent binding of transcriptional factors to the promoter regions. An enhancer may also provide an entry site, a point at which RNA polymerase/other essential protein associates with chromatin. It involves the

same type of interaction with the basal apparatus as the interactions promoted by the upstream promoter elements.

UAS are found in yeast, which are analogous to enhancers of higher eukaryotes. The UAS are located upstream of the gene in a region having two identical sequences of 72 bp each repeated at tandem 200-bp upstream of the initiation start site. The −72 bp repeat is located in a hypersensitive site of chromatin.

RNA polymerase I transcribes the genes for ribosomal RNA from a single type of promoter. The promoters for RNA polymerase I have the least diversity in the eukaryotic genome. The promoter has been found located 70-bp downstream of a control element called as UCE (upstream control element). The promoter consists of a bipartite sequence in the region preceding the start site which surrounds the start site extending from the −45 to +20 bp and is able to start the transcription. The UCE that is located at −180 to −107 bp increases the efficiency of the promoter. Both regions are enriched in GC contents. Two initiation factors are required for initiation of transcription by RNA polymerase I. The upstream binding factor 1 (UBF 1) binds in a sequence-specific manner to related sequences in the core promoter and UCE. Another factor called SL1 binds cooperatively to UBF 1 to extend the region of DNA. After binding of both the factors, RNA polymerase is able to initiate transcription after binding with the promoter region. The SL1 is specific species wise, for example, mouse SL1 cannot work on a human DNA. It consists of four proteins including one called TBP required for initiation of transcription by RNA polymerase II and III too. The SL1 has been considered analogous to sigma factor of bacteria.

RNA polymerase III transcribes DNA coding for 5S rRNA, tRNA, and many small nuclear RNAs. The DNAs transcribed by RNA polymerase III are all smaller in size, generally less than 300 nucleotides. The regulation of oocyte 5S rRNA synthesis has been studied. It requires three transcription factors for initiation called as TF IIIA, TF IIIB, TF IIIC. The TF IIIA is a member of zinc finger proteins whereas TF IIIB consists of TBP and two other proteins. The TF IIIC is still used as a partially purified preparation containing 5 subunits. It has been shown that TF IIIA is specific for oocyte 5S rRNA whereas, TF IIIB and TF IIIC are required for transcription of all the DNA by RNA polymerase III.

Promoters recognized by RNA polymerase III are of two types, lying upstream and lying downstream from the initiation site. These promoters are recognized by different initiation factors. The promoters for 5S rRNA and tRNA genes lie downstream to start site, whereas promoters for small nuclear RNAs gene located upstream from the start point. The promoters for 5S rRNA gene are located between −55 to +80 within the gene.

The promoters for RNA polymerase III have bipartite structure. The two short sequences are separated by a variable sequence. Type I promoter consists of box A sequence separated from a box C sequence and type II promoter consists of a box A sequence separated from a box B sequence. In Type II promoters, TF IIIC recognizes box B but binds to a region involving box A as well as box B. In Type I promoters, TF IIIA binds on box C. In both Type I and II promoters, binding of TF IIIC facilitates the binding of TF IIIB to the sequence surrounding the start site. It has been shown that TF IIIB is the main initiation factor for RNA polymerase

III, whereas TF IIIA and TF IIIC assist TF IIIB to bind at the correct site. The efficiency of the transcription by RNA polymerase is found to get increased by the presence of proximal sequence element (PSE). All the transcription factors for RNA polymerase bind at the promoter region forming preinitiation complex before the binding of RNA polymerase III on to the promoter.

3 RNA Splicing

Most eukaryotic genes have been found to have noncoding sequences (introns) in addition to coding sequences (exons). Introns are present in DNA and in the primary transcription product of the gene (HnRNA). The introns are removed by RNA splicing before mature mRNA is transported to the cytoplasm. The number of introns varies between the genes. The *dystrophin* gene has 70 introns whereas, α-interferon gene has no intron. The size of the intron also varies from nearly 100 nucleotides to 200 000 nucleotides.

There are at least four types of reactions of RNA splicing: splicing of nuclear introns, group I and II introns, and tRNA introns. Each reaction carries a change within the individual RNA molecule, therefore, is considered a cis-acting event. In RNA splicing, only very short consensus sequences are required. The required sequences are the end sequences of the intron, GT-AG. In yeast, a branch sequence UACUAAC is also required which is less conserved sequence in mammals. The ends of the introns are identified by RNA–RNA base pairing between the HnRNA and uridine rich small nuclear ribonucleoprotein particles called as snRNPs. Since the conserved splice site sequences are short and not precisely conserved between introns, and occur frequently in the primary sequences of many HnRNAs, this allows the spliceosomes to combine different 5′ and 3′ splice sites in HnRNA to produce several alternatively spliced mRNAs from a single nuclear gene. Therefore, due to the process of alternate splicing, multiple proteins with different primary amino acid sequences and biological activities may be produced from a single gene. The alternatively spliced mRNAs have been shown to be regulated in either at temporal, development, or tissue-specific manner in many cases. An alternatively RNA splice site choice is shown to be used to regulate expression of somatic sex determination pathway in *Drosophila*. The sex lethal and the transformer 1 proteins have been shown to control the maintenance of sex by regulating *Drosophila* gene expression at the level of alternative RNA splicing.

The RNA splicing starts with at 5′ splicing site and formation of a lariat occurs by joining GU end of the intron to the A position of the branch sequence via a 5′,2′ linkage. Afterward, 3′-OH end of the exon attacks the 3′ splicing site in such a way that ligation of exons occurs releasing intron as a lariat. Both reactions involve trans-esterification in which bonds are conserved. At several stages, ATP hydrolysis occurs probably for the conformational changes in the RNA and/or proteins. Lariat formation is responsible for 3′ splicing site. Nuclear splicing requires formation of a spliceosome, which contains various snRNPs and splicing factors. SnRNPs recognize consensus sequences and also share some interacting proteins. The U1, U2 and U5 snRNPs each contain a single snRNA and several proteins, whereas U4/U6 snRNP contains two snRNAs and several proteins. The U1 snRNP base pairs

with the 5′ splicing site, U2 base-pairs with the branch sequence, U5 snRNP acts at the 5′ splicing site. From U4/U6, there is cleavage of U4 and afterward, U6 base-pairs with U2. All this creates the catalytic center for splicing. Group I and Group II introns perform RNA splicing as a self-catalyzed property of RNA. In Group I introns, required for attack at the 5′ exon–intron junction is provided by a free guanine nucleotide whereas in Group II introns, it is provided by an internal 2′-OH position. These introns also follow GT-AG rule, but form a characteristic secondary structure that holds the splice sites in the appropriate position. The tRNA splicing in yeast has been shown to involve separate endonuclease and ligase reactions. The endonuclease recognizes the secondary structure of the pre-tRNA and cleaves both ends of the intron. The two halves-tRNAs released by the removal of introns can be ligated using the enzyme RNA ligase in the presence of ATP.

3.1 Nuclear Splicing

In eukaryotes, majority of genes have introns. Because of the presence of introns (noncoding sequences) in the gene, there is much discrepancy in size between the nuclear genes and their corresponding mRNAs. The average size of nuclear RNA (HnRNA) was found to be much larger and more complex than mRNA. The HnRNP has also been found to be a ribonucleoprotein in which HnRNA is bound by proteins such that it looks like a bead connected by a fiber. The beads are globular-shaped RNA associated with six common proteins, A1, A2, B1, B2, C1, C2, called as *core proteins*. The size of the core proteins ranges from 34 000 to 120 000 daltons. The exact structure of the HnRNP and the function of RNAs packaging in the form of beads are not clear.

The RNA splicing and other posttranscriptional changes occur in the nucleus and the substrate for these processes is HnRNP. The transcript is capped at the 5′ end, introns removed, polyadenylation at the 3′ end. As such all these reactions are called RNA processing. The RNA after processing is transported through the nuclear pores to the cytoplasm where it is available for translation.

There are many types of splicing systems (Fig. 10):

1. Introns are removed from the nuclear RNAs using spliceosome. The reaction requires a large splicing system.
2. Excision of certain introns is an autonomous property of the RNA itself. The ability of RNA to act as an enzyme is seen in the self-cleavage of viroid RNAs and in the catalytic activity of RNase P.
3. The removal of introns in yeast pre-tRNAs involves endonuclease and RNA ligase whose dealings with pre-tRNA seem to resemble those of the RNA-processing enzymes. A critical feature is the conformation of pre-tRNA.

Nuclear RNA splicing junctions are interchangeable but are read in pairs. There is no extensive homology or complementarity between the two ends (5′ GU – AG3′) of an intron. As written above, the junctions have well-conserved consensus sequences. The really high conservation is found only within the introns at the presumed junctions. The 5′ and 3′ end dinucleotides sequence define the left (or 5′) and right (or 3′) splicing sites, and these are also called donor and acceptor sites. It has been shown that there is a common mechanism for nuclear HnRNA splicing.

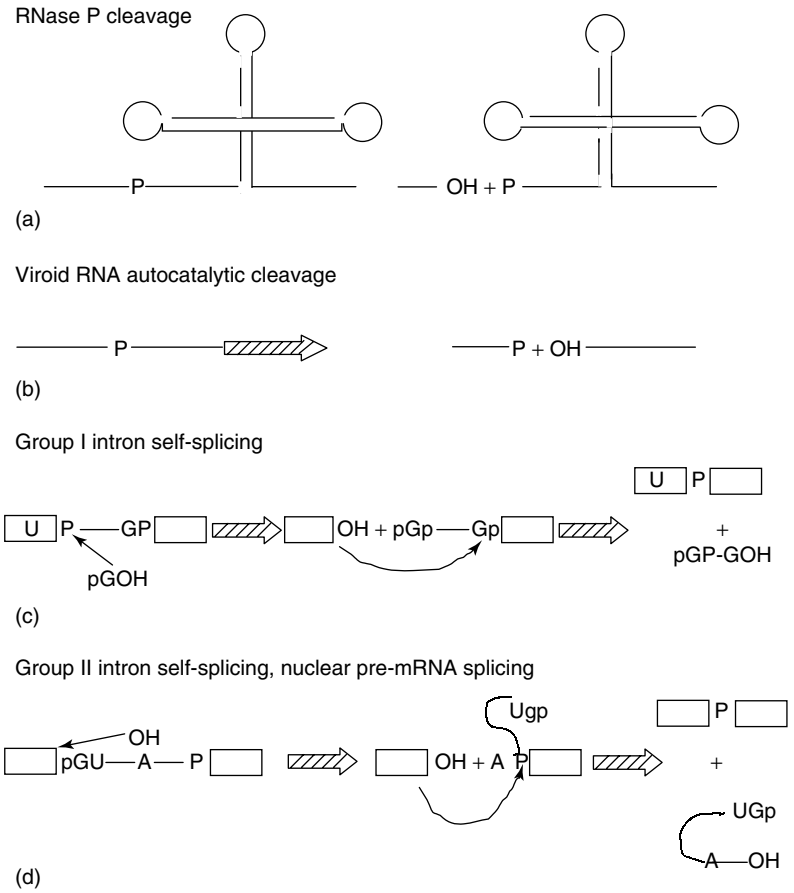

Fig. 10 Different types of RNA catalyzed intron splicing reactions.

However, the consensus is not applied to the introns of mitochondria, chloroplasts and pre-tRNA introns.

To ensure splicing of the correct pairs of junctions, the following two points may be applicable:

1. It could be the intrinsic property of the RNA to connect the sites at the ends of a particular intron, because of the base-pairing involving these regions.
2. All the 5′ sites may be functionally equivalent and all 3′ sites may be similarly indistinguishable. The splicing could follow rules ensuring that 5′ site is always connected to the 3′ site that comes next in the RNA.

The splicing sites are generic; they do not have specific individual RNA precursors. Besides, the apparatus (spliceosome) for splicing is not tissue specific. RNA may be spliced by any cell and the conformation of the RNA influences the accessibility of the splicing sites. The reaction also does not proceed sequentially along the precursor. RNA splicing is also independent of modifications to the RNA. *In vitro*, a cut is first made at the 5′ end of the intron

separating the left exon and the right intron–exon molecule. The left exon takes the form of a linear molecule whereas the right intron–exon is not a linear molecule. The 5′ terminus generated at the left end of the intron becomes linked by a 5′-2′ bond to the A in the branch site located 30 nucleotides upstream of the 3′ end of the intron. This linkage keeps the intron in the form of a structure called as lariat. Afterward, cutting at the 3′ end releases the free intron in a lariat form and right exon gets ligated with the left exon. The lariat is then debranched to give a linear excised intron, which is rapidly degraded.

3.2 Spliceosome and Small Nuclear RNAs

Many small RNAs have been found in the nucleus and cytoplasm of eukaryotic cells, called as small nuclear RNAs (snRNAs) or snurps and small cytoplasmic RNAs (scRNAs) or scrps, respectively. A small nuclear ribonucleoprotein particle (snRNP) generally contains one snRNA and about 10 proteins. Some of the proteins are common in all the snRNPs while some of the proteins are unique to a particular snRNP. The common proteins are recognized by an autoimmune antiserum (anti-Sm) and are considered to be involved in the autoimmune reaction. Many snRNPs are involved in RNA splicing. The snRNAs present in these snRNPs have sequences complementary to the 5′ or 3′ splicing sites or to the branching sequence. It is considered that base-pairing between snRNA and HnRNA or between snRNAs plays an important role in splicing.

The spliceosome consists of many snRNPs and many additional proteins often called as splicing factors (Fig. 11). The snRNPs are U1, U2, U5, U4/U6 named according to the snRNPs present in the spliceosome. The snRNPs present in spliceosome together have about 40 proteins. Some of these proteins may be directly involved in splicing and others may have structural roles for assembly or for interaction with the snRNPs.

In U1 snRNP, a region of 5′ terminal 11 nucleotides that is single-stranded and has a stretch complementary to the consensus sequence at the 3′ site of the exon is considered to be directly involved in splicing. The intact U1 snRNP can bind to a 5′ splicing site *in vitro*. Only snRNA of U1 cannot bind with the 5′ splicing site. The U1 RNP first binds at the 5′ splice site, then it also binds to the branch site. How U1 RNP recognizes to the branch site is not known. The U2 RNA binds to the branch site by recognizing base-pairing interaction. However, for binding of U2 RNP, prior binding of U1 RNP is essential. Although interaction with U1 snRNP is responsible for recognizing the splicing site, it does not control the cleavage. Initially, U5 snRNA binds close to exon sequences at the 5′ splice site, then it changes its position to the vicinity of the intron. From the results, it has been suggested that snRNA components of snRNPs interact both among themselves and with the substrate RNA by base-pairing interactions, and these interactions allow for changes in structure that may bring reaction groups into opposition and create catalytic center.

A series of loci containing genes potentially coding for splicing factors were originally thought to code RNA, but are now known to encode pre-RNA processing proteins (PRP). Some of the PRP are components of snRNPs and others may function as independent factors. A protein, PRP16, an ATP-dependent helicase has been shown to be involved

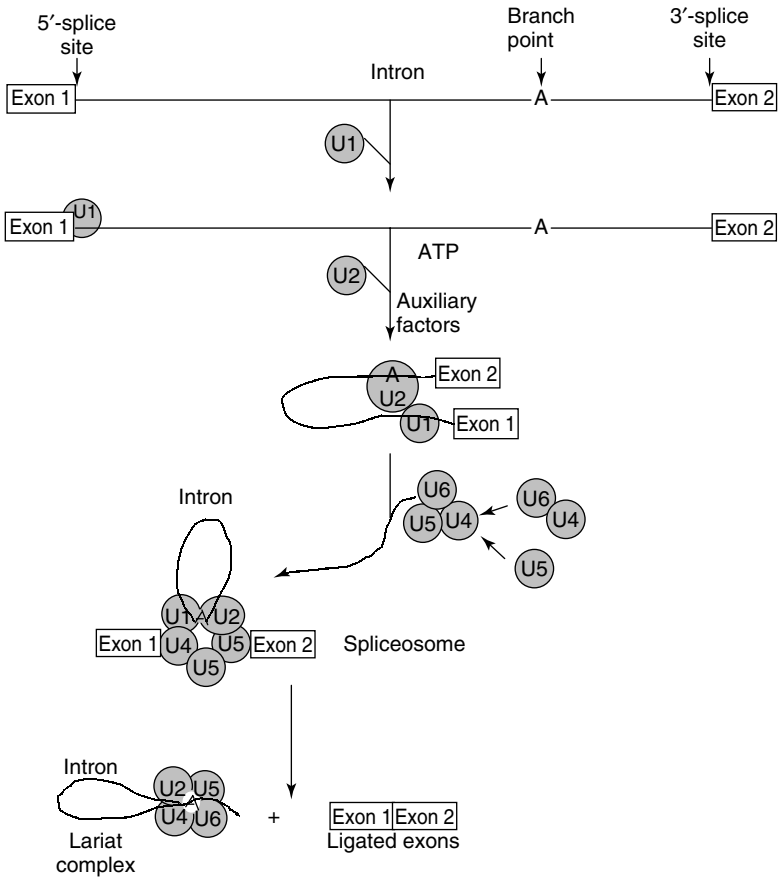

Fig. 11 Pre-mRNA splicing using spliceosome. The spliceosome formation involves the interaction of component that recognizes the consensus sequences. U1, U2, U3, U4, U5 & U6 are different small ribonuclear proteins.

in the second catalytic step of RNA splicing. Another PRP22, another ATP-dependent helicase has been shown to be required to release mRNA from the spliceosome.

3.3 Group I and Group II Introns

The splicing is a two-stage reaction: 5′ exon-intron junction is attacked by a hydroxyl group and secondly the hydroxyl group that has been transferred at the 5′ exon end attacks the 3′ intron–exon junction.

Group I introns (where hydroxyl group is provided by a free guanine nucleotide) are more common than Group II introns (where hydroxyl group is provided by an internal 2′-OH position). Both Group I and II introns can perform the splicing by itself without requiring enzymic activities provided by the proteins. Group II mitochondrial introns have splicing sites resembling the nuclear introns. They are also spliced by the same mechanism as

nuclear HnRNA. Two trans-esterification reactions can be performed by the Group II introns. The number of phosphodiester bonds is conserved in the reaction; therefore, external supply of energy is not required. This could have been an important feature in the evolution of splicing. In autocatalytic splicing, RNA folds into a specific conformation or series of conformations and splicing occurs in cis-conformation. In contrast, snRNAs act in trans form upon HnRNA.

Cech and Group while working with *Tetrahymena thermophila* for the first time found that RNA molecules are capable of self-RNA splicing without the involvement of any protein. Such type of RNA was called as *ribozyme* by them, which means RNA as an enzyme. They showed that RNA could catalyze its own splicing. The self-splicing of RNA in *Tetrahymena thermophila* has been shown in Fig. 12. The enzymes act on other molecules other than on themselves, that's why they coined the term ''Ribozyme''. Cech and Group afterward also showed that ribozyme could act on a slightly different form of the same RNA; therefore, it is an enzyme in true sense. Cech also suggested that because of the fact that RNA acts as catalyst as well as informational molecule, when life originated RNA may have functioned without DNA or proteins.

3.4 Cis- and Trans-splicing Reactions

Splicing occurs generally as a cis-reaction. It is an intramolecular reaction where controlled deletion of the introns take place. Introns can be removed from RNA molecule allowing exons of the RNA molecule to be spliced together. There is also intermolecular splicing where exons present in different RNA molecules can be spliced (ligated) in one molecule, it is called trans-splicing (Fig. 13). The trans-reactions are rare and never occur between pre-mRNA transcripts of the same gene.

The trans-splicing occurs *in vivo* in some special conditions. In trypanosome, there is presence of a 35 nucleotide leader sequence at the end of many mRNAs. This RNA is called as spliced leader RNA (SL RNA). It donates the 5′ exon for trans-splicing. The SL RNAs found in species of trypanosomes and nematodes have common features. They fold into a common secondary structure having three stem loops and a single-stranded region resembling snRNPs. Trypanosomes possess the U2, U4, and U6 snRNAs but do not have U1 and U3 snRNAs. SL RNA functions without participation of the recognition of the 3′ splicing site and depends directly on RNA.

Some chloroplast genes are also trans-spliced. The *psa* gene of *Chlamydomonas* chloroplast has three widely separated exons. Exon 1 is located 50 kb away from Exon 2 and Exon 2 is 90 kb away from Exon 3. Many other genes lie between these exons. These cannot be transcribed as a common transcript since Exon 1 is in reversed orientation from Exon 2 and Exon 3. Several other genes are required for one or the other of trans-splicing reactions, so the process of splicing this mRNA together is quite complex.

3.5 tRNA Splicing

All the genes coding for tRNAs do not have noncoding sequences (introns) in their structures. Only about 40 out of nearly 400 nuclear tRNA gene products in yeast are interrupted. In each interrupted tRNA gene product, only one intron present just one nucleotide beyond the 3′ side

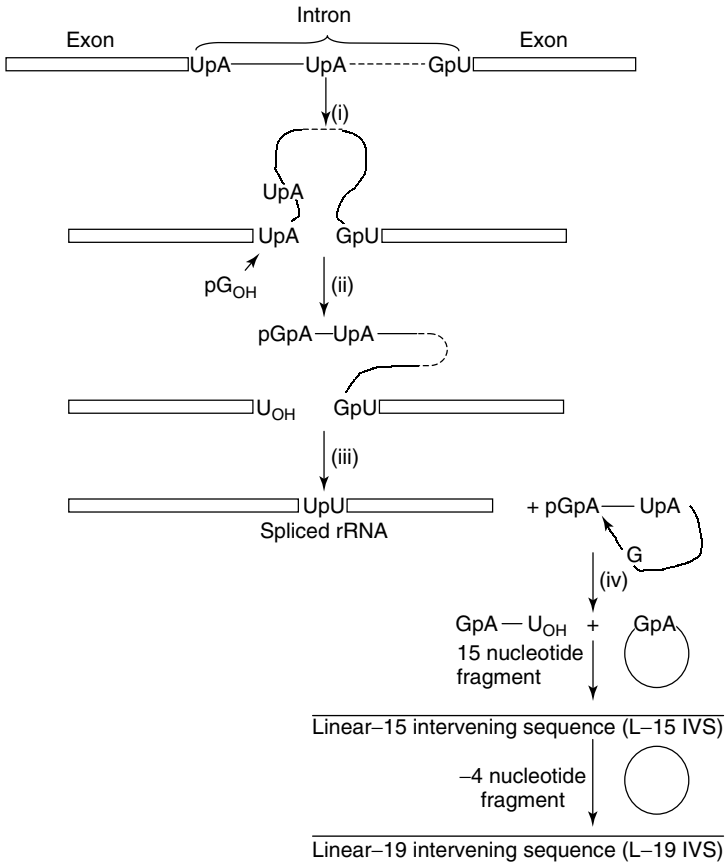

Fig. 12 Self-cleavage of rRNA intron: the intron of pre-rRNA of *tetrahymena* is cleaved by autocatalytic splicing. (1) Folding of RNA to act as ribozyme; (2) a hydroxyl group attached to GTP attacks the 5′ end phosphate of the intron and the phosphodiester bond between exon and intron is broken and a new bond is formed between the guanine nucleotide and the intron; (3) the hydroxyl group at the left exon attacks at the 3′ end of intron. The bond is broken and the exons are ligated releasing the intron; (4) a similar reaction enables the intron to form a circle, snipping 15 nucleotides off its end in the process. The circle opens into a linear molecule and then closes with the removal of four nucleotides. The final open form is called L-19 IVS (linear minus 19 intervening sequence).

of the anticodon has been found. The size of these introns varies from 14 to 46 nucleotides. No consensus sequence has been found in these introns. RNA splicing in the primary transcript of tRNA gene occurs in a different way. There is a separate cleavage and ligation reaction (Fig. 14). The same mode of splicing as in yeast has been reported to the nuclear tRNA gene products of plants, amphibians, and mammals. All the introns in tRNA gene products have a sequence complementary to the anticodon of the tRNA. This is an alternative

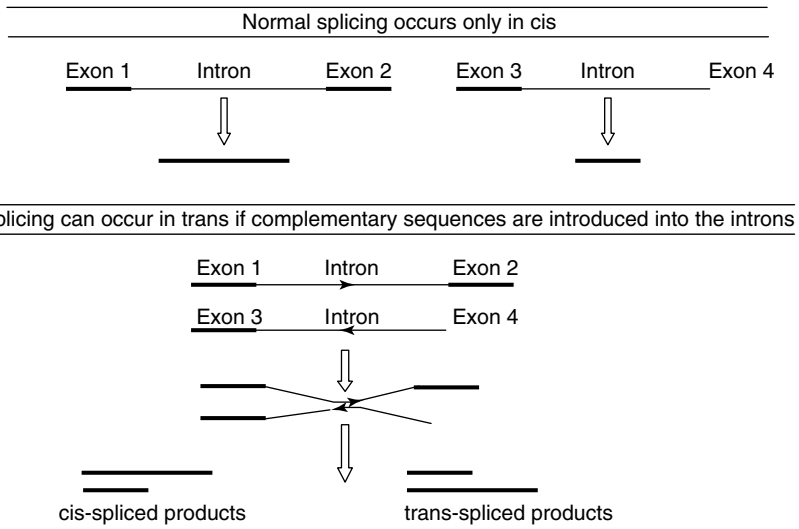

Fig. 13 Schematic diagram showing cis-splicing and trans-splicing reactions.

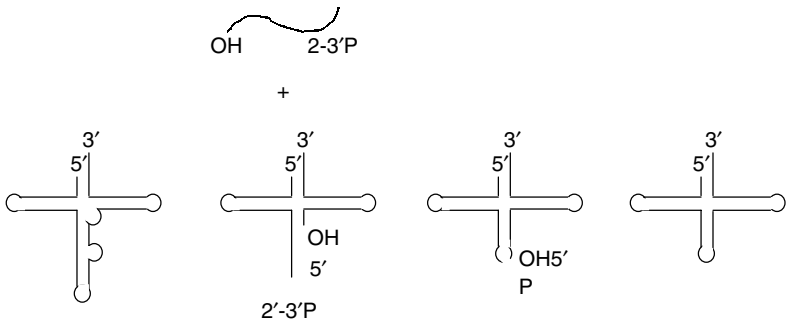

Fig. 14 Splicing of tRNA. It involves cleavage of exon-intron boundaries by endonuclease to generate 2′-3′ cyclic phosphate and 5′-OH termini. The cyclic phosphate is opened to generate 3′-OH and 2′ phosphate group. The 5′-OH is phosphorylated and after releasing the intron, the tRNA half molecule folds into a tRNA-like structure that now has a 3′-OH and 5′ phosphate which is then joined by RNA ligase.

conformation for the anticodon arm in which the anticodon is base-paired to form an extension of usual arm. Splicing of tRNA gene product depends primarily on recognition of a common secondary structure in tRNA. No common sequence in the introns has been reported.

In tRNA gene product splicing, there is cleavage of phosphodiester bond with the help of an endonuclease and no ATP hydrolysis is required. Afterward, an enzyme called as RNA ligase is required for bond formation and ligase reaction requires energy in the form of ATP hydrolysis. Generation of a 2′, 3′ cyclic phosphate bond also occurs during splicing in plants and mammals. On cleavage of phosphodiester bond as a result

of endonuclease reaction, first there is generation of 2′, 3′ cyclic phosphate and 5′-OH termini. The cyclic phosphate is opened to form 3′-OH and 2′ phosphate groups and 5′-OH is phosphorylated. After releasing the intron, the tRNA half molecules fold into a tRNA like structure that has a 3′-OH, 5′-phosphate which gets sealed by RNA ligase.

Ribonuclease P is a tRNA processing enzyme found both in bacteria and eukaryotes. It is a nucleoprotein. Earlier, it was shown that both the RNA and protein components are required for the nuclease to cut the tRNA precursor at a specific point. However, afterward, it was shown that only RNA part of Ribonuclease P may cut the pre-tRNA molecule at a specific site. On the other hand, the protein part alone could not do this indicating that RNA catalyzes the splicing of pre-tRNA molecule.

3.6 Alternate Splicing

When a single gene gives more than one mRNA sequences, it is called alternate splicing. In some cases, use of different start point (5′ splicing site) and/or 3′ splice site alters the pattern of splicing. As written above, this occurs because of only dinucleotide sequences at the ends of the introns. As a result, it is possible that the same portion of the gene may act as exon in one mRNA and as intron in other mRNA. Alternate splicing also occurs because of substitution, addition or deletion of internal exons. For example, if a gene has exon number 1,2,3,4,5,6,7,8, these may be ligated in different ways like 1,2,3,4; 2,3,5,7; 1,2,4,6; 1,2,3,7; 1,3,5,6, and so on. The multiple products are made in the same cell but in others the process is regulated so that particular splicing patterns occur only under certain conditions. Proteins that intervene to bias the use of alternate splice sites have been identified in some cases. In recently sequenced human genome, the number of genes has been estimated in the range of 26,000 but total number of proteins in different stages of development has been estimated to be nearly 500 000. This situation has been explained on the basis of alternate splicing. It has been estimated that from one gene under different conditions, nearly 20 proteins may be coded.

In *Drosophila melanogaster*, native splicing may be caused by mutations in the genes. In case of T/t antigens, the 5′ site for the T antigen removes a termination codon present in t antigen mRNA. That's why the size of T antigen is more than of the t antigen. In E1A transcripts, one of the 5′ sites connect to the last exon in a different open-reading frame which causes change in the C-terminal region of the protein.

Drosophila flies with one X chromosome and two sets of autosomes are male while with equal number of chromosomes and sets of autosomes are female. The X : A ratio activates the so called Sxl which controls positively its own expression as well as that of three other genes. This provides a mechanism so that a single X chromosome of males is transcribed into as much RNA as the two X chromosomes of females. The *Sxl* gene produces male- or female-specific spliced transcripts. They have identical 5′ ends but differ in the presence or absence of a small male specific exon that inserts a stop codon into the transcript. The protein encoded by *Sxl* gene has an eighty amino acid RNA binding domain. The same motif has been reported in many other RNA

binding proteins. It perhaps provides the clue of control of its own processing and that of further proteins in the regulatory cascade.

4
Posttranscriptional Regulation of mRNA

Although regulation of gene expression in eukaryotes at the level of initiation of transcription is considered to be most important, regulation at the level of post-transcription has also been noted in many cases. Capping at the 5′ end of the eukaryotic mRNA is considered to be important. However, polyadenylation at the 3′ end has not been found in all the mRNAs. Whether inhibition of polyadenylation is specifically used to block expression of particular genes is not known. Some genes have multiple putative polyadenylation sites which may be used for alternate splicing (formation of more than one mRNA from one gene). Besides, the choice of polyadenylation site may vary during development of a cell. Switching of splicing patterns may occur in a developmentally significant way.

Polyadenylation does not occur at the extreme 3′ end of mRNA. In fact, between 10 to 30 nucleotides are transcribed preceding the polyadenylation signal which is having the sequence 5′AAUAAA3′ or a variant of it. These terminal nucleotides are cleaved with the help of an endonuclease producing an intermediate 3′ end to which the polyA tail is subsequently attached by the enzyme poly A polymerase. For polyadenylation, there is requirement of a specificity factor too that recognizes the 5′AAUAAA3′ sequence. The specificity factor has three subunits which together bind specifically to RNA containing the sequence 5′AAUAAA3′. The poly A polymerase first synthesizes nearly 10 residue oligo A at the 3′ end of mRNA in the presence of specificity factor. Afterward, this oligo A tail is extended to nearly 200 residues in the presence of an another factor which recognizes oligo A tail and directs poly A polymerase to extend it. As written above, polyadenylation of mRNA is not essential for further translation. It is considered that it may affect the stability of mRNA in the cell. The poly A tail is associated with a particular protein called as poly A binding protein (PABP). It is believed that binding of poly A with PABP is essential for protection of mRNA against degradation by nucleases.

Besides, the stability of mRNA may be regulated in the cytoplasm. This may result in changes in its concentration. It has been found that estrogen hormone not only induces the transcription of vitellogenin gene but also increases the stability of its mRNA in the cytoplasm increasing its half-life to 300 h from 16 h.

All the mRNAs in eukaryotes are found to have 5′ cap. Although the exact significance of capping is not clear, it is considered that it is a recognition point for the attachment of a ribosome at the outset of translation. It is considered equivalent to Shine Dalgarno sequence, GGAGGC, found in prokaryotes to which the small subunit of ribosome attaches to start protein biosynthesis. The ribosome recognizes the cap structure as its binding site, and after attachment migrates along the mRNA until it reaches the initiation codon. It is also found that mRNAs that are translated on the cytoplasmic ribosomes are capped. There is no capping in mitochondrial and chloroplasts mRNAs.

In eukaryotes, a mRNA after splicing at the 5′ end has 5′pppPuNp----3′, where Pu is a purine residue, N is the sugar component of the nucleotide and p represents the phosphate group. However, mature mRNA (after posttranscriptional changes) at the 5′ end has 5′-7-mGpppPuNp----- 3′, where 7 mG is 7-methyl guanosine which is attached after transcription and is called a *cap*. During capping, there is cleavage of the terminal phosphate group of the first nucleotide catalyzed by a phosphohydrolase. Afterward, a guanylyl residue is transferred at the 5′ end from GTP by the enzyme, guanylyl transferase and thereafter, modified to 7-methyl guanylyl residue by the enzyme mRNA, guanylyl-7-methyl transferase in the presence of *S*-adenosyl methionine which acts as methyl donor. The newly added guanylyl residue is in the reverse orientation compared to other nucleotides present in mRNA. A cap containing single methyl group is known as *cap o*. If there is addition of another methyl group on the second nucleotide, which was in fact the first nucleotide in the original mRNA, it is called *cap 1*. This occurs only if it is adenine nucleotide. The methyl group is added on the N^6 position of adenine nucleotide. This reaction is catalyzed by the enzyme 2′-*O*-methyl transferase and methyl group donor is same, that is *S*-adenosyl methionine. In some cases, even there is addition of another methyl group to the third nucleotide. The substrate for this reaction is cap 1 mRNA, and acceptor of the methyl group is ribosyl moiety at 2′position. This is called as *cap 2*. The number of caps is considered to be characteristic of the organism. In addition, a low frequency of internal methylation (1 in 1000 nucleotides) also occurs in the mRNA of higher eukaryotes.

In prokaryotic mRNA, generally posttranscriptional changes do not occur. Because of no compartmentation, there may be coupled translation (as soon as mRNA biosynthesis occurs, or even in progress, it may bind with the ribosome to start translation).

5
Transport of Processed mRNA to the Cytoplasm

After posttranscriptional modifications, matured mRNA is transported out of the nucleus in a very rapid process. After coming in the cytoplasm, mRNA binds on the cytoplasmic ribosomes for translation within 1 to 5 min after leaving the nucleus. It is considered that some specific proteins help mature mRNA in transporting it out of the nucleus but exactly how it occurs is not known.

6
Regulation of Gene Expression at the level of Translation

Most of the regulation of gene expression takes place at the level of transcription. Production of mRNA requires many steps, several of which like promoter utilization, RNA splicing, polyadenylation, are known to be regulated. Pre-mRNA stability and the transport of mRNA from the nucleus to the cytoplasm provide a very rapid control of gene expression. Sometimes, the level of translation is manipulated by changing essential components of the translational machinery of the cell. The phosphorylation of ribosomal components (particularly 5S rRNA in the 40S ribosomal subunit) has been correlated with higher polysome levels after

the presence of different growth factors in the mammalian cells. Similarly, in the brine shrimp egg, upon fertilization, an all of a sudden appearance of a previously missing translational initiation factor takes place that is involved in the formation of polysome.

Besides, in mammalian reticulocytes, the control of protein synthesis by hemin is mediated by the formation of a potent inhibitor of polypeptide chain initiator called as hemin controlled repressor (HCR) from a presynthesized precursor (prorepressor). These cells have lost their nuclei, but retain high levels of stable mRNAs encoding mostly hemoglobin chains. In reticulocyte lysates, protein synthesis occurs at a high rate but declines rapidly if hemin is absent. In cells, hemin is synthesized in the mitochondria, which are not present in the lysate. In fact, in the absence of heme, HCR gets activated, whereas, in the presence of heme, HCR gets inhibited. Although the mode of action of HCR was mysterious for many years, now it has been found that it acts as a specific kinase for the phosphorylation of the α subunit of translation initiation factor 2. Because of the initiation factor 2 (eIF2), GTP-GDP exchange cycle, phosphorylation of even a fraction of eIF 2 is sufficient to stop initiation of protein synthesis. Apparently, all of the eIF2B, which is present in lower amount than the amount of eIF2, becomes sequestered into eIF2–eIF2B complexes and is no longer available to recycle the remaining unphosphorylated eIF2.

A translational inhibitor has also been reported from Friend Leukemia cells. The inhibitor has been characterized as heat labile, sulfhydryl reagent insensitive protein of the molecular weight nearly 214 000 daltons. It inhibits initiation of protein synthesis by preventing initiation factor dependent binding of methionyl-tRNA to 40S ribosomal subunit. However, it does not interfere with the formation of ternary complex between the eIF2, methionyl-tRNA and GTP. The inhibitor in fact acts as protein kinase, which phosphorylates the α subunit of eIF2. This inhibitor has been considered analogous to HCR of reticulocyte cells.

An enzyme protein having phosphoprotein phosphatase activity capable of releasing the phosphate group from the phosphorylated α subunit of eIF 2 has also been reported from the rabbit reticulocyte cells. Therefore, it may restore the activity of eIF 2 lost after phosphorylation. Activity of this phosphoprotein phosphatase has been shown to be stimulated about threefolds by optimal concentration of Mn^{+2} ions, but is not stimulated by Ca^{+2} or Mg^{+2} ions. The enzyme is strongly inhibited by Fe^{+2} and by purine nucleoside diphosphates.

During posttranslational modifications, many proteins are modified by phosphorylation, acetylation, hydroxylation, and so on at the side chains of the amino acids. In many proteins, there is conjugation of nonprotein component(s).

Other strategies that act at or before the translation initiation step are alteration in the inherent variability in the life span of eukaryotic mRNA and mRNA stability in response to certain agents.

Keywords

Basement Membrane
Thin layer of extracellular matrix, often rich in collagen type IV, which separates epithelia from connective tissue; also called *basal lamina*.

Germline
The lineage of cells that give rise to gametes, which carry the genetic material that will be transmitted to the next generation.

Knockout Mouse
Genetically modified mouse in which a particular gene has been deleted (in the case of a conditional knockout mouse, the gene is selectively deleted within particular cells or tissues of an otherwise wild-type animal), in a time and/or spatially controlled manner.

Model Organisms
Organisms that have characteristics, such as short life cycles, ready availability, and/or tractability, which make them particularly well suited for laboratory study of biological processes. Because of the great degree of evolutionary conservation of molecular pathways and cellular processes, the large amount of information derived from the study of model organisms can often be applied to the analysis of human development, physiology, disease, and evolution.

Niche
Term used to describe the cellular microenvironment in which stem cells reside and which provides a unique combination of signaling molecules essential for the maintenance of stem cells; the niche hypothesis was first proposed by Schofield in 1978 to explain the regulation of hematopoietic stem cells.

Self-renewal
The ability of a stem cell to indefinitely replenish itself through cell divisions that are followed by the maintenance of stem cell character in at least one of the daughter cells.

Transgenic Animal
Animal carrying genetic material (transgene) introduced into its genome using genetic engineering techniques.

Transit Amplifying Cells
Stem cell progeny that have a limited potential for mitotic divisions and are not yet fully differentiated.

Stem cells are essential for the health of multicellular organisms, as they give rise to all cells of the body during embryonic development, and in adults, maintain the integrity and function of many tissues. Stem cells are functionally defined as cells that have the extended ability to self-renew and to give rise to various cell types present in a given tissue. The behavior of stem cells is remarkably context dependent, underscoring both the existence of complex regulatory mechanisms involved in their maintenance and function, as well as the inherent difficulties of studying their biology in a nonadulterating manner. Despite these difficulties, intense research has revealed that their regulation is achieved via the orchestration of cell-intrinsic factors, locally secreted factors, and extrinsic signals impinging on the tissue. As knowledge of the mechanisms of stem cell regulation expands through the combined study of powerful model systems, we will continue to gain valuable insights into how to manipulate stem cells for the welfare of human kind.

1 Introduction to Stem Cell Biology

Stem cells have been main characters in media reports for the past several years, reflecting their awe-inspiring properties and potential for clinical applications. Despite their importance and the attention they have received from many basic, applied, and clinical scientists, however, stem cells remain difficult to recognize, to study, and even to define. Morphological and molecular markers are scarce and not available for all types of stem cells, and studies so far indicate that no intrinsic stem-specific marker exists that unifies all stem cells and sets them apart from all other cells in the body. The scarcity or absence of markers coupled with the relatively low numbers at which stem cells normally occur leads to their being defined on a functional basis, namely, that they are cells with the potential to undergo a very large number of divisions to self perpetuate and give rise to different cell types in an embryo or tissue. Many layers of regulation are required for maintaining stem cell properties and tailoring their functions to the needs of the tissues in which they reside. Although much is still unknown, considerable progress has been made in recent years in unraveling the mechanisms of stem cell regulation, largely resulting from the use of many different systems of study, ranging from invertebrate model systems to human stem cells. Continued investigation of the regulation of stem cells will provide the pillars on which to build our basic knowledge of stem cell biology, from which informed strategies for their clinical application will be derived.

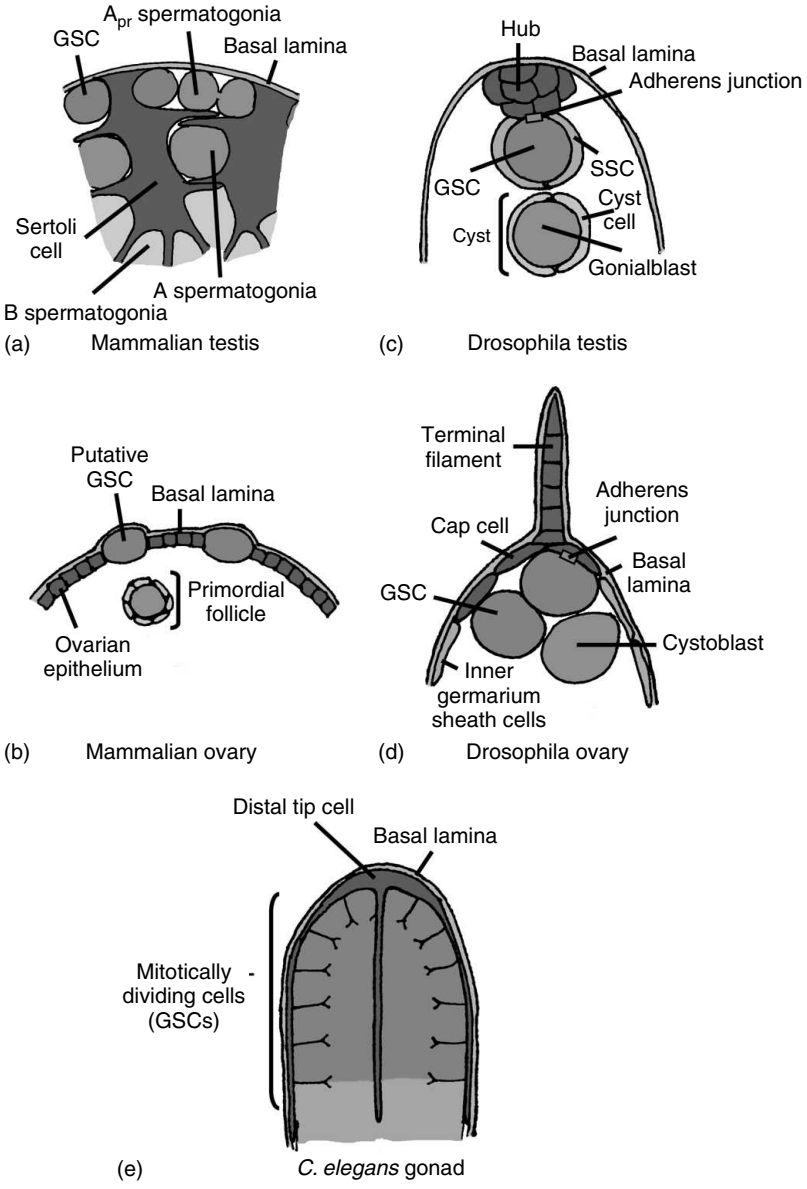
2 Adult Stem Cells

2.1 Germline Stem Cells

2.1.1 Mammalian Testis

During embryonic development, pluripotent primordial germ cells are set aside and associate with the developing gonad, and a fraction of them gives rise to germline stem cells (GSCs). In males, GSCs are

active throughout adult life, leading to the constant production of sperm within seminiferous tubules. The proper function of GSCs requires a signaling environment (or niche) provided by closely associated Sertoli cells, which are large somatic cells (Fig. 1a). Although Sertoli cells extend processes radially from the basement membrane to the lumen, contacting all germ cells, their asymmetric secretion of signals creates gradients along their extended processes. The interstitial area of the testis,



surrounding the basement membrane of the seminiferous tubules, also contains steroid-secreting Leydig cells as well as myoid cells.

Premeiotic male germ cells are called spermatogonia, and these are divided into undifferentiated A-type spermatogonia and differentiating spermatogonia. GSCs correspond to the earliest undifferentiated stage, A_{single} (A_s) spermatogonia, located at the periphery of seminiferous tubules in low numbers. A_s spermatogonia divide to self-renew and give rise to daughter cells that undergo four rounds of divisions remaining in clusters of 2 cells (A_{paired} [A_{pr}] spermatogonia), and subsequently 4, 8, and 16 cells (collectively called $A_{aligned}$ [A_{al}] spermatogonia). The spermatogonia subsequently differentiate through A1, A2, A3, and A4 intermediate stages into B spermatogonia, which undergo meiosis and form sperm. As they progress through spermatogenesis, germline cells move to the center of the tubules, culminating in the final release of sperm into the lumen.

Male GSCs, or A_s spermatogonia, can be recognized by their location and behavior. A_s spermatogonia show longer cell cycles and asynchronous divisions because they are not present in clusters. They are also present near the basement membrane, closely associated with Sertoli cells. The gold standard for the functional identification of stem cells is the ability of transplanted cells to repopulate testes of an infertile host, thereby restoring long-term fertility. On the basis of transplantation assays, the number of GSCs in normal testes was estimated at 2 per 10^4 germ cells. For transplantation assays, testis cells from fertile mice or rats are harvested, and the cell suspension is microinjected into seminiferous tubules of a host treated

Fig. 1 Germline stem cells. (a) In the mammalian testis, low numbers of germline stem cells (GSCs), also called A_{single} (A_s) spermatogonia, are located at the periphery of seminiferous tubules near the basal lamina and in close contact with large somatic sertoli cells. GSCs renew themselves and also give rise to daughter cells that form cysts of 2 (A_{paired}, A_{pr}), 4, 8, and 16 cells ($A_{aligned}$, A_{al}). They subsequently differentiate through A and B spermatogonia, which undergo meiosis and form sperm. (b) In the mammalian ovaries, putative GSCs reside in the periphery of the ovary, within the ovarian epithelium, juxtaposed to the basal lamina. These putative GSCs are thought to renew themselves and give rise to daughter cells that associate with follicle cells to form new primordial follicles in adult females. The existence of these mammalian female GSCs, however, is highly controversial. (c) The Drosophila testis is surrounded by a basal lamina and contains a signaling center, called the hub, at its apical tip. Five to nine GSCs are attached to the hub cells via adherens junctions, and each GSC is also in close association with a pair of surrounding somatic stem cells (SSCs). GSCs divide asymmetrically, perpendicular to the hub, to give rise to a new GSC (near the hub) and a gonialblast (away from the hub). The gonialblast is associated with a pair of somatic cyst cells derived from the SSCs, and it divides to form germline cysts that differentiate into sperm. (d) In each germarium within the Drosophila ovary, two to three GSCs are present in a microenvironment or niche, formed by somatic terminal filament and cap cells in close association with a basal lamina. GSCs are in close association with cap cells via adherens junctions, and they divide asymmetrically to renew themselves and generate cystoblasts. In a region surrounded by inner germarium sheath cells, each cystoblast divides to give rise to a germline cyst containing a future oocyte. (e) In the distal end of the *C. elegans* gonad, the distal tip cells extend long processes and are in close contact with syncytial germline cells that divide mitotically to renew themselves, implying that they include GSCs. In addition, germline cells generated in this distal region move more proximately, away from the distal tip cell, and eventually undergo meiosis to form oocytes.

with busulfan (a chemotherapeutic drug that depletes testes of GSCs) or carrying a sterility-causing mutation. Injected GSCs populate sites along the basement membrane of the seminiferous tubules and establish colonies of donor GSC-derived cells supporting sperm production. Subpopulations of germline cells can also be isolated based on the expression of combinations of proteins by fluorescence-activated cell sorting, and subsequently subjected to transplantation assays to determine whether they include GSCs, allowing the identification of molecular markers enriched in A_s spermatogonia.

Although no marker specifically labeling A_s spermatogonia has been identified to date, $\alpha 6\beta 1$ integrins (which may help attach GSCs to the basement membrane), and Neurogenin 3 (a class B basic helix-loop-helix (bHLH) transcription factor) are enriched in A_s spermatogonia, which also lack c-kit expression. Recently, analysis of the classic *luxoid* mutant showed that A_s spermatogonia renewal is impaired and germ cells are lost; mutation of the gene *Zfp145*, which encodes the zinc finger–containing transcription factor Plzf, was found to be responsible for the phenotype. Plzf is coexpressed with the transcription factor Oct 4 in undifferentiated spermatogonia.

Sertoli cells produce a variety of signals, such as glial-cell-line-derived neurotrophic factor (GDNF), insulin-like growth factor 1 (IGF-1), transforming growth factors (TGFs) α and β, epidermal growth factor (EGF), and Steel factor. GDNF, however, is the only secreted factor produced by Sertoli cells known to be required for A_s spermatogonia maintenance. Decreased levels of GDNF, caused by gene targeting of one copy of the GDNF gene, result in Sertoli cell-only seminiferous tubules, reflecting a depletion of germ cells. Conversely, transgenic mice overexpressing GDNF under a testis-specific promoter, display large clusters of undifferentiated spermatogonia resulting from a block in differentiation. Studies using a serum-free culture system for GSC showed that GDNF acts directly on undifferentiated spermatogonia, which express the receptor for GDNF (composed of GDNF-family receptor $\alpha 1$ and c-Ret receptor tyrosine kinase), to stimulate GSC self-renewal. In addition, bone morphogenetic protein (BMP) 8B is expressed in early germ cells, and knockout mouse experiments suggest that it is required for the establishment of GSCs as well as their proliferation and maintenance.

Other secreted factors are required for germline differentiation. Steel factor, which is produced by Sertoli cells, acts on the c-kit receptor of spermatogonia to promote proliferation of differentiating type A spermatogonia. Pituitary luteinizing hormone (LH) and follicle stimulating hormone (FSH) influence the differentiation of spermatogonia, acting indirectly via supporting somatic cells, but no direct effects of these hormones on undifferentiated spermatogonia are known. In response to LH, Leydig cells secrete testosterone, which in turn acts on Sertoli cells. FSH plus testosterone stimulate secretion by Sertoli cells of signals required for germ cell differentiation.

The mammalian testis is a powerful system to understand the regulation of stem cells. The availability of transplantation assays, in which the ability of donor GSCs to reconstitute the ablated germline of the host is tested, provide a rigorous system for dissecting the *in vivo* requirement of different factors for GSC function. Insights obtained from this system have direct implications for human fertility.

2.1.2 Mammalian Ovary

For over half a century, it has been widely accepted that adult mammalian ovaries do not contain self-renewing GSCs. This dogmatic view, however, was recently challenged by experiments suggesting that GSCs may in fact be present in adult mouse ovaries. Putative GSCs with large ovoid shape that reside in the surface epithelial cell layer covering the ovary are thought to divide mitotically to generate germline cells that enter meiosis and give rise to new follicles in adult females (Fig. 1b). These putative GSCs may play a central role in replenishing the follicular population of the ovary as follicles undergo a high rate of atresia or degeneration. Similar to GSCs in the testis, the ovarian GSCs are sensitive to busulfan-treatment, and they also appear capable of contributing to follicle formation upon transplantation of ovarian fragments from one female to another. These findings may hold true in human females as well, and this is an area of investigation. The possible existence of GSCs in female adults suggests that the decreased fertility observed in older females may be because of stem cell senescence and/or impaired function.

The data suggesting the presence of GSCs in mammalian ovaries, however, remains highly controversial. Definitive demonstration that female GSCs exist will require lineage tracing experiments to show that single putative GSCs can indeed give rise to daughter cells that contribute to follicle formation in adult females. In addition, it will be very important to understand what cell types and molecules are required for establishing, maintaining, and regulating GSCs, and to determine their mechanism of function.

2.1.3 Drosophila Testis

Drosophila germline precursor cells (''pole cells'') are formed early during embryogenesis and later populate the gonads. A fraction of the pole cells give rise to GSCs, which can be identified by their morphology, location, and behavior. The Drosophila testis is a simple tube with 5 to 9 GSCs located in a circle at its closed apical end that are in close contact with a compact, dome-shaped structure called the hub, which is composed of 8 to 16 somatic cells (Fig. 1c). Each GSC is enclosed by a pair of somatic stem cells (SSCs) known as cyst progenitor cells that send out cytoplasmic projections that contact the hub. Lineage tracing experiments have confirmed that the GSCs indeed function as stem cells. GSCs divide asymmetrically to self-renew and give rise to a gonialblast, which is surrounded by a pair of cyst cells resulting from the asymmetric division of the SSCs to form a germline cyst. As the germline cells progress through spermatogenesis, they remain surrounded by the pair of postmitotic cyst cells. The gonialblast divides four times with incomplete cytokinesis to form a cyst of primary spermatocytes that enter meiosis to form spermatids and, ultimately, sperm.

Drosophila GSCs, gonialblasts, and early germline cysts have a specialized subcellular structure called the fusome, which is rich in the cytoskeletal proteins Hu li tai shao (Hts, an adducin-like protein), α-spectrin, β-spectrin, and ankyrin. In GSCs and gonialblasts, the fusome is round and often referred to as a spectrosome, whereas in germline cysts, it becomes elongated and branched. GSCs and gonialblasts do not express Bam (encoded by the *bag-of-marbles* gene), a differentiation factor expressed in two-cell to early 16-cell germline cysts.

The hub is an important component of the GSC niche in the Drosophila testis, providing important signals regulating GSC maintenance and function. As GSCs divide, mitotic spindles are oriented perpendicular to the hub such that one daughter cell (the GSC) remains in contact with the hub, whereas the other (the gonialblast) is placed in a distinct environment away from the hub. The orientation of GSC division requires the Drosophila homolog of the adenomatous polyposis coli (APC) tumor suppressor, presumably via the interaction with DE-cadherin and Armadillo (the homolog of β-catenin) for the formation of adherens junctions between hub cells and GSCs.

Genetic analysis has identified several factors required for GSC maintenance and function. An important signal secreted by the hub is the ligand Unpaired (Upd). GSCs unable to respond to Upd due to a lack of *stat92E* (encoding Drosophila Signal Transducer and Activator of Transcription [STAT]) function are not maintained as stem cells, but instead differentiate. Conversely, overexpression of Upd in the testis results in accumulation of undifferentiated, GSC-like cells away from the hub. These data demonstrate that Upd acts on neighboring GSCs to activate the Janus kinase (JAK)-STAT pathway, resulting in maintenance of GSC status, while gonialblasts, which are not exposed to high levels of Upd, can undergo differentiation.

Other signals are also important for GSC maintenance and differentiation. Hub cells and somatic cyst cells express the BMP molecules Glass bottom boat (Gbb, also known as 60A) and Decapentaplegic (Dpp), and these signaling molecules together activate the BMP pathway directly in male GSCs to control their maintenance, at least in part, via the repression of Bam expression. In addition, disruption of EGF signaling in somatic cyst cells disrupts differentiation of gonialblasts, resulting in accumulation of undifferentiated germ cells in the testis. Somatic cyst cells also signal to germline cysts via a TGF β-like signaling pathway to limit the number of mitotic divisions during cyst formation. Finally, proliferation of germ cells is also controlled by the germline-expressed genes *bam* and *benign gonial cell neoplasm* (*bgcn*).

Remarkably, when the GSC niche is depleted of GSCs via the transient inactivation of the JAK-STAT pathway, dividing germline cysts can dedifferentiate into GSCs that repopulate the niche. In these experiments, a temperature-sensitive allele of *stat92E* was employed; at the nonpermissive temperature, loss of *stat92E* function resulted in loss of GSCs because of their differentiation into gonialblasts and subsequent formation of germline cysts. Restoration of JAK-STAT signaling by returning GSC-depleted males to the permissive temperature resulted in a breakdown of dividing germline cysts into single cells that repopulated the hub as GSCs. These experiments revealed a great degree of plasticity in this system.

The knowledge of the precise location of GSCs and surrounding niche cells in the Drosophila testis, as well as the ability to follow their behavior and apply powerful genetic tools to the study of GSCs, makes this an ideal experimental system to further examine their maintenance and regulation.

2.1.4 Drosophila Ovary

Drosophila females produce eggs throughout most of their adult lives, and egg production is supported by both germline and somatic stem cells. Each ovary is composed of 15 to 20 ovarioles, which are strings of progressively older egg chambers that contain the developing eggs.

Somatic and GSCs reside at the anterior-most tip of each ovariole in a structure called the germarium, within which the egg chambers are formed (Fig. 1d). The division of a GSC generates a daughter cell called a cystoblast, which undergoes four rounds of division with incomplete cytokinesis to form a 16-cell cyst. The posterior-most cell within a cyst will become the oocyte, and the remaining 15 cells will become nurse cells that support the growth and development of the oocyte. As the cyst progresses through the germarium, it acquires a layer of follicle cells derived from the somatic stem cells. A round cyst surrounded by a monolayer of follicle cells buds off from the germarium as an egg chamber, which continues to develop as it progresses posteriorly through the ovariole.

GSCs are located near several populations of somatic cells, namely, terminal filament cells, cap cells, and inner germarium sheath cells. These cells create a niche crucial for stem cell maintenance and function. GSCs contact cap cells and inner sheath cells, and they divide asymmetrically to generate a stem cell in its original position and a cystoblast in a slightly posterior position, such that the cystoblast contacts inner sheath cells, but not cap cells. GSCs and cystoblasts contain a round spectrosome, whereas older cysts within the germarium contain branched fusomes. GSCs do not express Bam, whereas cystoblasts and early dividing germline cysts express this differentiation factor.

Signals from the niche control GSC maintenance and function. Adherens junctions formed by DE-cadherin and armadillo are present between cap cells and GSCs. Genetic analysis suggests that this molecular ''glue'' is important for the maintenance of GSCs, presumably by physically keeping them within the niche environment. Dpp is a pivotal signal expressed in somatic niche cells. Ectopic Dpp expression results in increased numbers of GSC-like cells within the germarium. Dpp acts directly on GSCs as evidenced by the fact that elimination of the function of signaling pathway components (e.g. Dpp receptors encoded by *punt* and *tkv* or downstream transcriptional factors encoded by *Mad* and *Med*) specifically within the germline disrupts GSC maintenance and division. Gbb is also expressed in somatic cells near GSCs, but overexpression of Gbb is not sufficient to induce GSC tumors within the germarium. Reduced Gbb levels, however, result in reduced activation of the BMP pathway in GSCs, suggesting that Gbb may cooperate with Dpp for optimal levels of GSC activation. Dpp and Gbb activate a signal transduction cascade in GSCs that results in direct binding of the downstream Mad-Med Smad protein complex and repression of expression of the Bam differentiation factor. Repressing Bam expression in GSCs is crucial: if Bam expression is forced in these cells using a heat-shock inducible *bam* transgene, they undergo differentiation. In addition, Bam and the ubiquitin protein ligase Smurf, appear to play redundant roles in restricting the domain of Dpp receptor activation, suggesting the existence of multiple mechanisms that ensure that only GSCs respond to the Dpp signal.

Several other factors are also required for GSC maintenance. Nanos is required to establish and maintain GSCs by preventing their differentiation, as removal of Nanos function in the germline of adult females results in loss of GSCs. *Pumilio* mutant flies also show loss of GSCs. On the basis of their functions during early embryogenesis, Nanos and Pumilio presumably form

a complex that binds to the 3′ untranslated region of target mRNAs to repress their translation. The *piwi* gene encodes a conserved protein expressed in niche cells as well as in GSCs. Expression of *piwi* within somatic cells is required for GSC maintenance, whereas it is required within the germline to control GSC division and germline development. The *fs(1)Yb* gene is required to maintain *piwi* expression in terminal filament and cap cells.

As in the Drosophila testis, dedifferentiation of germline cysts into GSCs has been reported in the ovary. In these experiments, a pulse of Bam expression caused larval germ cells, which are present in a Dpp-rich environment, to form cysts. After removal of Bam, four- and eight-cell cysts present in second instar larval ovaries were found to break down and form single germline cells that gave rise to normal GSCs, supporting oogenesis in the resulting adult females. Similarly, a pulse of Bam expression in adult ovarioles overexpressing Dpp resulted in GSC differentiation and cyst formation, and these cysts were also capable of breaking down into single GSCs. These results, coupled with those in the Drosophila male testis, suggest that, under specific conditions (e.g. a Dpp-rich environment), differentiated cells may serve as a source of stem cells.

The investigation of GSC regulation in the Drosophila ovary has greatly advanced the field of stem cell regulation. The power of genetics, the easy identification of GSCs and surrounding niche cells, and the ability to measure the behavior of GSCs and their progeny will continue to make this an excellent system to establish new paradigms of GSC regulation. Insights from the Drosophila ovary will be instrumental in forging ahead with the investigation of the putative GSCs present in the mammalian ovary.

2.1.5 *Caenorhabditis Elegans* Gonad

In the *Caenorhabditis elegans* hermaphrodite, the adult gonad is a U-shaped tube containing mitotically dividing germ cells at the distal ends of the anterior and posterior arms. The germline forms a syncytium, such that each cell is connected via a cytoplasmic bridge to a core of cytoplasm (rachis) that is present along the center of the distal gonad arm (Fig. 1e). These mitotically dividing germline cells self-renew and give rise to cells that progress through meiosis to produce oocytes; however, a stereotypic stem cell has not yet been identified. At a ~20-cell diameter distance from the distal tips of the gonad, cells enter meiosis and progress into meiotic divisions as they move proximally within the gonad arms. A distal tip cell is in close contact with each distal end of the gonad, providing a niche environment that regulates the balance between mitosis and meiosis, while sheath cells surround more proximal regions of each gonad arm.

The distal tip cell is required for the establishment and maintenance of GSCs, because distal tip cell ablation results in meiosis and differentiation of all germline cells, while its relocation results in the coordinate ectopic location of mitotically dividing germline cells. The distal tip cell produces LAG-2: a Notch receptor ligand. This signal is received by germline cells at the distal end of the gonad, activating the GLP-1/Notch signaling pathway in distally located germline cells, which causes them to remain in mitosis. Constitutive activation of the GLP-1/Notch pathway in the germline inhibits exit from mitosis and entry into meiosis, resulting in a tumorous germline, whereas mutations in Notch pathway components lead to premature entry into meiosis. Activation of the

GLP-1/Notch pathway inhibits accumulation of the RNA-binding protein GLD-1 via the translational inhibitors NOS-3 (similar to Drosophila Nanos) and FBF-2 (similar to Drosophila Pumilio). GLD-1 levels are important in controlling the decision between proliferation (low GLD-1) or meiosis (high GLD-1). GLP-1/Notch signaling also inhibits the *gld-3* gene, a homolog of *Bicaudal-C*, via the FBF-2 translational repressor. GLD-3 binds to the poly-A polymerase GLD-2, and together they help promote the transition from mitosis to meiosis.

Despite the current view that the distal mitotic germline population as a whole maintains stem cell properties, it is not clear whether all mitotically dividing cells within that population are equivalent, or whether only specific cells have stem cell properties. Lineage analysis will be required to distinguish between these mechanisms and represents an important step towards a full understanding of how these syncytial GSCs are regulated.

2.2 Epithelial Stem Cells

2.2.1 Mammalian Epidermis and Hair Follicles

In the mammalian epidermis and hair follicles, differentiated cells are continuously lost and replaced by cells derived from stem cells. In the interfollicular epidermis, dividing keratinocytes are found in the basal layer attached to the basement membrane (Fig. 2a). As keratinocytes move away from the basement membrane towards the surface of the skin, they stop dividing, undergo differentiation into spinous and granular layer cells, and finally die, thereby forming the heavily keratinized stratum corneum. In mouse skin, the entire differentiation process from the basal layer to the keratinized stratum corneum takes 10 to 14 days, whereas in human skin this process takes longer.

Rare stem cells are thought to reside in the basal layer of the epidermis, in regions that express high levels of the Delta1 ligand for Notch and of $\alpha 6\beta 1$ integrins, suggesting that interactions with the extracellular matrix may be important for their regulation. Indeed, $\alpha 6$ and $\beta 1$ RNAs are found to be upregulated in stem cell-enriched populations relative to other mitotically dividing cells, whereas $\beta 1$ integrin can be used as a marker during cell sorting procedures for enrichment for stem cells. Stem cells give rise to actively dividing transit amplifying cells that subsequently undergo differentiation through the layers of the epidermis. Although the stem cell population renews itself, there is no evidence for invariant asymmetric divisions, suggesting that each stem cell division can give rise to any combination of stem cell and transit amplifying cells. In addition, long-term maintenance of this stem cell population is likely to require mobilization of bulge stem cells, which reside in the hair follicles (see below).

The hair follicle is composed of concentric layers: the outer root sheath (ORS), which is an extension of the epidermis, the inner root sheath (IRS), and the hair shaft (Fig. 2a). The IRS and hair shaft are derived from relatively undifferentiated matrix cells. Matrix cells are in close contact with the dermal papilla, which is composed of mesenchymal cells. Although matrix cells are actively dividing, their proliferation potential is limited. The stem cells that sustain long-term hair follicle growth cycles are a distinct population thought to reside in a structure called the bulge. Bulge cells are undifferentiated

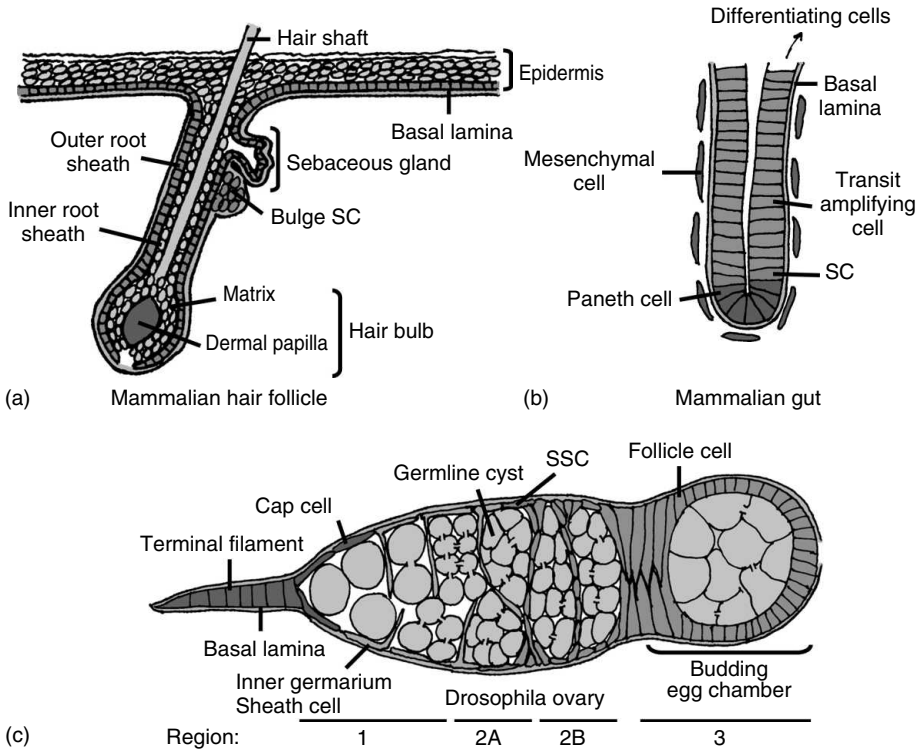


Fig. 2 Epithelial stem cells. (a) The mammalian hair follicle contains multipotent stem cells (SCs) in a region called the bulge, below the sebaceous gland, and the entire follicle is surrounded by a basal lamina. Bulge SCs give rise to transit amplifying matrix cells, which have a limited proliferation potential and give rise to differentiating cells that produce the hair shaft. Matrix cells surround the dermal papilla, which is an important signaling center for the bulge SCs. During the catagen phase of the hair follicle cycle, the lower part of the follicle undergoes extensive cell death, and as a result, the dermal papilla moves toward the bulge. After the telogen rest period, signals from the dermal papilla mobilize SCs from the bulge to regenerate the matrix and reinitiate the anagen growth phase. (b) The basal region of the mammalian gut crypt contains stem cells (SCs) above differentiated Paneth cells, and a basal lamina and mesenchymal cells surround the entire crypt. New cells produced from the basal SCs migrate up and, once they exit the crypt, begin differentiating into various intestinal cell types. (c) The Drosophila ovary germarium contains two somatic stem cells (SSCs) that contact a basal lamina as well as inner germarium sheath cells. In addition, SSCs respond to signals produced by the terminal filament and cap cells. As SSCs divide, they renew themselves and also generate daughter cells that further divide and surround newly formed 16-cell germline cysts, supporting oocyte development.

cells that lie at the base of the epithelial portion of the hair follicle and are present throughout the hair follicle growth cycles. Bulge cells are thought to have a large proliferation potential on the basis of the size of colonies formed in culture. *In vivo*, however, the proliferation of bulge cells is tightly regulated, and they rarely divide. Because bulge stem cells are slow cycling, they can be experimentally identified as

"label-retaining cells." In this procedure, all cells in the epithelium are initially labeled by a continuous supply of tritiated thymidine or bromodeoxyuridine (BrdU), which becomes incorporated into the DNA as cells divide. After a long chase period, the label is diluted and lost from all rapidly dividing cells (e.g. matrix transit amplifying cells), whereas the slowly dividing bulge stem cells retain the label. This strategy has been used both in lineage tracing experiments and to obtain highly purified bulge stem cell populations.

Each hair follicle growth cycle includes an active growth phase (anagen), a destruction phase (catagen), and a rest period (telogen), with the length of different phases varying according to the type of hair follicle and the specific organism. During anagen, the active proliferation of matrix cells gives rise to cells that move upward and differentiate to form IRS and hair shaft cells. During catagen, the lower part of the follicle undergoes extensive cell death and, as a result, the dermal papilla moves towards the bulge. After the quiescence of the telogen, signals from the dermal papilla leads to recruitment of cells from the bulge, which gives rise to matrix cells that reinitiate the cycle.

Bulge-residing stem cells give rise not only to hair follicle cells, but also to cells of the epidermis and sebaceous glands, in a highly regulated process. In particular, bulge stem cells are mobilized to repopulate interfollicular epidermis upon wounding of the epidermis, and it is likely that they also give rise to the interfollicular epidermal stem cells in normal situations. Evidence for the multipotency of stem cells in the bulge comes from both transplantation assays and lineage tracing analysis. Recent experiments have shown that two distinct populations of bulge-residing stem cells exist. One population maintains contact with the basement membrane, the other is suprabasal and arises later, after the start of the first postnatal hair cycle. Although these populations show different gene-expression profiles, they behave similarly within the niche, have the ability to self-renew *in vitro*, and can form epidermis and hair when grafted.

Although the signals regulating bulge stem cell activity are incompletely understood, recent genetic profiling of purified bulge stem cells performed by two groups suggests possible mechanisms for their quiescent, multipotential character. Bulge stem cells express elevated levels of cell cycle regulatory proteins and keratinocyte growth inhibitors such as TGF β signaling components. Indeed, TGFβ receptor activation, as measured by the levels of nuclear phosphorylated Smad2 (a downstream effector), appears to be elevated in bulge cells relative to their progeny. Conversely, transcripts for proliferation-associated proteins are downregulated in bulge stem cells. Bulge stem cells also express high levels of fibroblast growth factor (FGF) 1 and its receptor, suggesting a role for the FGF1 pathway in maintenance of stem cell character.

Wnt signals appear to play a dual role in the transition from bulge to matrix cell type. Both bulge cells and matrix cells receive Wnt signals, resulting in stabilization and increased levels of β catenin; however, the cellular outcome of Wnt signaling is different in bulge versus matrix cells, presumably due to expression of distinct β catenin binding partners. Bulge cells express Tcf3, which normally acts as a transcriptional repressor when complexed with β catenin, suggesting a Wnt-repressed niche for bulge stem cells. In contrast, matrix cells express Lef1, which, when associated with β catenin

results in transcriptional activation of downstream targets. Downstream targets of β catenin – Lef1 complexes involved in switching from rarely dividing bulge cells to actively dividing matrix cells include c-Myc and cyclin D.

Wnt signaling via Lef1 is also required for hair shaft differentiation of matrix cells, and establishment of Lef1 expression in matrix cells requires noggin, a BMP-inhibitor secreted by the dermal papilla. These observations suggest that transient repression of BMP signaling is required to make matrix cells responsive to Wnt signals. Subsequently, however, BMP signaling via the BMP receptor IA is required for stabilization of β-catenin in response to Wnt stimulation such that both pathways act together to induce the expression of hair differentiation–inducing genes.

As the complex roles of different signaling pathways are unraveled and new players are identified, our understanding of the hair follicle stem cell system will continue to expand. In addition, new technologies are currently being developed to allow the introduction of transgenes into hair follicle cells for potential therapeutic use.

2.2.2 Mammalian Gut Crypts

The inner lining of the small intestine and colon is a simple columnar epithelium that forms invaginations called crypts of Lieberkuhn and projections called villi. The intestinal epithelial cells are turned over at a high rate, with new cells being produced from stem cells present at the base of the crypts (Fig. 2b). Stem cell-derived transit amplifying cells migrate up, and once they exit the crypt, begin differentiating into absorptive epithelial columnar cells, goblet cells, and enteroendocrine cells. Differentiated cells continue to migrate up and are shed from the tips of the villi, taking 5 to 7 days from crypt base to villus tip. Paneth cells originate from the same precursor cells as do other differentiated cells; however, Paneth cells migrate toward the bottom of the crypt instead.

Crypts are composed mostly of undifferentiated cells, and on the basis of lineage tracing studies and label-retaining properties, 4 to 5 stem cells have been shown to reside at the fourth or fifth cell positions from the base of each crypt in the small intestine, above differentiated Paneth cells. Paneth cells are long lived and produce a number of factors such as EGF and tumor necrosis factor α; however, ablation of Paneth cells does not appear to have any effect on crypt cell production. Stem cells are present in regions enriched for $\beta 1$ integrin (crypts express $\alpha 2\beta 1$, in contrast to villi, which express $\alpha 3\beta 1$ integrins), suggesting that adhesion to the extracellular matrix is important.

The Wnt pathway, acting via Tcf4/β catenin complexes, plays an important role in stimulating proliferation in the gut. Normal proliferating cells accumulate β catenin in the nucleus. In Tcf4 null mice, all epithelial cells differentiate, and no proliferation occurs. In addition, if expression of the secreted Dkk1 inhibitor of Wnt molecules is targeted to the proliferative compartment of the mouse intestine, epithelial proliferation is greatly reduced, resulting in the loss of crypts. Conversely, mutations in APC or β-catenin that stabilize β-catenin-Tcf4 complexes occur in the vast majority of human colon cancers and are sufficient to cause intestinal adenomatous polyp formation in mice.

Among the downstream factors of the Wnt pathway in the intestine are c-myc, SOX9 and Eph/Ephrin. c-myc pathway components are enriched in stem cells,

and c-myc is thought to act via the inhibition of the $p21^{CIP/WAF1}$ cell cycle inhibitor. SOX9 is expressed in proliferating, undifferentiated cells, and appears to repress the differentiation-inducing genes CDX2 and MUC2. The ephrin receptor EphB2 is expressed in proliferating cells, decreasing in a gradient towards the top of the crypts, whereas EphB3 expression is restricted to all cells below the stem cells, including Paneth cells. Ephrin-B1 and ephrin-B2 are expressed at the crypt-villus junction, decreasing toward the base of the crypt. This compartmentalization of Eph/Ephrin expression is thought to control the localization of Paneth cells as well as the separate placement of proliferating versus differentiated cells along the crypt-villus axis. In *EphB3* null mice, Paneth cells no longer migrate downwards, whereas in *EphB2/EphB3* double mutants, the proliferative and differentiated cells intermingle.

BMP signals also have a role in homeostasis of the intestine via inhibition of Wnt signaling. BMP4 is expressed in mesenchymal cells, including those adjacent to the stem cells, whereas the BMP receptor IA is expressed along the epithelial cells in the crypt-villus axis, being highly expressed in the stem cell region but excluded from the proliferating zone in the upper crypt region. Noggin, a negative regulator of BMP, is expressed in a region adjacent to the crypt bottom and in some cells in the stem cell region. Transgenic mice constitutively expressing *Xenopus* Noggin in the intestine have increased proliferation within crypts and *de novo* crypt formation, showing similar intestinal histopathology to human patients with the cancer predisposition syndrome, juvenile polyposis. Conditional inactivation of BMP receptor IA in adult mice results in inactivation of PTEN (a tumor suppressor gene-encoded inhibitor of phosphatidyl inositol [PI]-3 kinase) and localization of β catenin to the nucleus (where β catenin forms a complex with Tcf proteins to activate transcriptional targets), also with a resulting expansion of the proliferative region. Similarly, treatment with Noggin also results in inactivation of PTEN and nuclear transport of β-catenin in *ex vivo* cultures, and a PI-3 kinase inhibitor antagonizes this effect. These results suggest that BMP inhibits proliferation of intestinal cells via the inhibition of β-catenin activity downstream of Wnt signaling.

Other signals from the underlying mesenchyme are also important for stem cell function in the gut. For example, mutations in *Fkh6*, a gene expressed in the mesenchyme underlying mid- and hindgut, result in altered crypt morphology and overproliferation. In addition, keratinocyte growth factor (KGF, a member of the FGF family) is thought to stimulate proliferation of gut epithelial cells, and FGF receptor-3 is expressed in undifferentiated, proliferating cells during crypt formation and regeneration.

2.2.3 Drosophila Follicle Cells

Somatic cells called follicle cells are crucial for germline development in females. In Drosophila, follicle cells are produced throughout adult life from somatic stem cells (SSCs) located in the germarium (Fig. 2c). Lineage tracing studies have demonstrated that two SSCs are located near the junction between regions 2a (corresponding to the location of early 16-cell cysts) and 2b (corresponding to the location of lens-shaped cysts spanning the entire width of the germarium). As these stem cells divide, they give rise to daughter cells that envelop newly formed 16-cell germline cysts to form egg chambers. The follicle cells continue to divide until stage

7 of oogenesis with a doubling time of approximately 10 h, and with their division rate coordinated with the division of SSCs.

The Hedgehog (Hh) signaling molecule plays an essential role in SSC regulation. Hh is produced in terminal filament and cap cells in the anterior portion of the germarium, and directly stimulates SSC division. Inactivation of Hh using a temperature-sensitive *hh* allele disrupts egg chamber budding and, as a result, germline cysts accumulate within the germaria. Conversely, excessive Hh signaling induced by overexpression of an *hh* transgene or inactivation of the Hh receptor Patched (a negative regulator of the Hh signaling cascade) results in excessive generation of somatic cells. Lineage analysis suggests that the excessive generation of somatic cells results from an increased number of SSCs.

The Wingless (Wg) signal, also produced in terminal filament and cap cells, is required for SSC maintenance as well. Specific inactivation of downstream components of the Wg signaling pathway within SSCs results in stem cell loss, indicating that direct activation of stem cells by Wg molecules is necessary for stem cell maintenance. Conversely, overexpression of Wg or inactivation of its negative regulators results in excessive somatic cell production. In addition, overexpression of Wg results in a variety of differentiation defects.

Other factors are also required for SSC maintenance. *fs(1)Yb* is a gene involved in regulation of somatic and germline stem cell divisions via the regulation of *hh* expression. SSCs also require DE-cadherin for their maintenance, and they are in close contact with some of the inner germarial sheath cells, suggesting that these may form a stem cell niche.

2.3 Neural Stem Cells

The mammalian brain was thought to be an entirely postmitotic organ until regions containing proliferating cells were identified and shown to contain neural stem cells (NSCs). NSCs are present in the subventricular zone of the lateral ventricle and in the dentate gyrus subgranular zone of the hippocampus (Fig. 3). Surprisingly, astrocytes, originally thought to be in the astroglial lineage, function as NSCs within these neurogenic regions. Subventricular zone astrocytes give rise to transit amplifying cells, which in turn give rise to committed neuroblasts (Fig. 3a). These neuroblasts migrate to the olfactory bulb, where they differentiate into interneurons. Subgranular zone astrocytes give rise to progenitor cells that mature into granule cells (Fig. 3b), which integrate in the dentate gyrus granule cell layer and may play a role in learning and memory.

The behavior of NSCs is regulated by a microenvironment or niche composed of a basal lamina (rich in laminin and collagen-1), endothelial cells from the vasculature and their associated perivascular fibroblasts and macrophages, and, in the subventricular zone, ependymal cells lining the lateral ventricle. High levels of β1 integrin are expressed on the surface of NSCs within neurospheres (aggregate cultures derived from single NSCs), suggesting that NSCs may associate with the basement membrane via an interaction between β1 integrin and laminin. Interestingly, astrocytes also serve as niche cells, producing signals necessary to maintain their own NSC properties. This adult niche retains signaling molecules that are used during development of the nervous system.

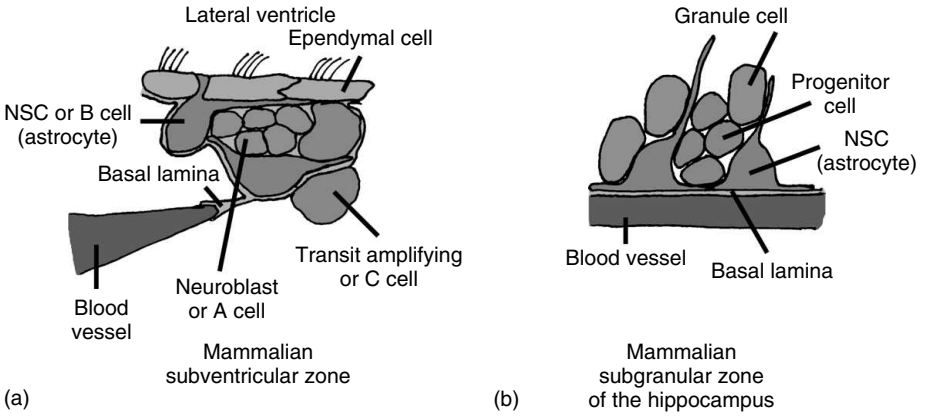

Fig. 3 Neural stem cells. (a) The subventricular zone of the adult mammalian brain contain astrocytes that function as neural stem cells (NSC), also called B cells. Some of these B cells contact the ventricle lumen, which is filled with cerebrospinal fluid and lined with ependymal cells. B cells generate transit amplifying C cells. C cells give rise to neuroblasts or A cells that migrate to the olfactory bulb and differentiate into interneurons. NSCs are regulated by a microenvironment created by astrocytes themselves (which have a dual role as NSC and niche cell), endothelial cells from local blood vessels, as well as associated fibroblasts and macrophages, and an intimately associated basal lamina. (b) The subgranular zone of the adult mammalian hippocampus also contains astrocytes that function as NSC. These astrocytes are in close proximity to blood vessels, which are presumably surrounded by an analogous basal lamina to the one found in the subventricular zone. Astrocytes divide to give rise to progenitor cells, which differentiate into granule cells that integrate nearby into the dentate gyrus.

NSCs are concentrated around blood vessels in the brain, and recent evidence points to endothelial cells, previously thought of as an exclusively structural component of blood vessels, as an NSC niche signaling component. *In vitro* studies have shown that endothelial cells produce diffusible factors that can promote self-renewal of NSCs, as well as prime them for differentiation into neurons and interneurons upon removal of such signals.

Many different signaling molecules are thought to contribute to maintaining the stem cell character of NSCs and regulating their neurogenic potential. Vascular endothelial growth factor (VEGF) receptors are expressed in neurogenic regions, and intraventricular VEGF infusions increase neuronal precursor proliferation. LeX, a carbohydrate moiety also known as CD15, is enriched in blood vessels and in a subpopulation of astrocytes in the subventricular and subgranular zones, and its expression is associated with subventricular zone cells that grow as neurosphere stem cells *in vitro*. Subventricular zone astrocytes also express ephrin B2/3 ligands, and intraventricular infusion of the EphB2 ligand results in increased astrocyte numbers. TGFα, an EGF receptor ligand, is expressed in the subventricular zone, and reduced TGFα activity results in decreased neuronal precursor proliferation, while activation of EGF receptors (by intraventricular EGF infusion) increases proliferation of transit amplifying cells. Genetically altered mice lacking the extracellular matrix protein tenascin C, which is normally highly expressed in the subventricular zone, have defective expression of EGF receptors in the subventricular zone

due to alterations in the response of NSCs to FGF2 and BMP4, and they also have altered numbers of NSCs that are prone to differentiation in culture.

Manipulation of Sonic hedgehog (Shh) activity *in vivo* and *in vitro* also suggests a role for this molecule in maintaining proliferation and neurogenic potential of either NSCs or the transit amplifying population. BMP signaling also occurs in regions with Shh activity, and it may also be important for maintenance of NSCs. Notch1 and its Jagged ligand are expressed in the subventricular and subgranular zones, and expression of an activated form of Notch in subventricular zone cells suppresses proliferation and differentiation of neuronal precursors. BMP and Notch activate the inhibitor of differentiation (Id) proteins in neuroepithelial cells, and this may be how they inhibit neural differentiation. Coculture of NSCs with endothelial cells stimulates neuroepithelial cell contact, activating Notch and Hes1 to promote self-renewal, suggesting that this mechanism may also operate *in vivo*. Ependymal cells in the subventricular zone produce Noggin (a negative regulator of BMP signaling), which helps regulate the niche. Wnt molecules, on the other hand, play a role in neuronal differentiation, as is the case during embryonic stem cell differentiation.

Niche signaling molecules presumably regulate intrinsic factors necessary for NSC activity. Bmi-1 and TLX are transcriptional factors that may play such a role. These proteins are expressed in the nervous system, and elimination of the function of either results in decreased proliferation of adult NSCs. Small, noncoding double-stranded (ds) RNAs play a critical role in neuronal differentiation. For instance, the NRSE/RE1 dsRNA binds to the NRSF/REST protein, which is a transcriptional repressor that inhibits neuronal gene expression in NSCs. This dsRNA-protein interaction alleviates this transcriptional repression, resulting in expression of neuronal genes and differentiation of NSCs. It is, however, unclear how the combination of signaling pathways regulates these and other factors.

2.4 Hematopoietic Stem Cells

Hematopoietic stem cells (HSCs) are among the best-studied stem cell systems. HSCs reside within the bone marrow inside the ''major'' bones (Fig. 4). About 0.05% of mouse bone marrow cells correspond to a lineage of long-term self-renewing HSCs (the ''true'' stem cells), which give rise to short-term self-renewing HSCs (equivalent to transit amplifying cells) that form multipotent progenitors without apparent self-renewing properties. Multipotent progenitors give rise to common lymphoid progenitors and common myeloid progenitors, which respectively give rise to all lymphoid and myeloid cells of the blood. Single long-term HSCs isolated from mice and humans are capable of regenerating the hematopoietic system of irradiated hosts through self-renewal and multilineage differentiation, and have been extensively used for therapeutic purposes.

Long-term HSCs are in close association, likely mediated by N-cadherin and β-catenin, with spindle-shaped osteoblasts lining the inner surface of trabecular bone in the marrow cavity (Fig. 4). The demonstration that these osteoblasts are a key component of the HSC niche came from the fact that variations in the number of osteoblasts directly correlate with variations in the number of HSCs. Inactivation of

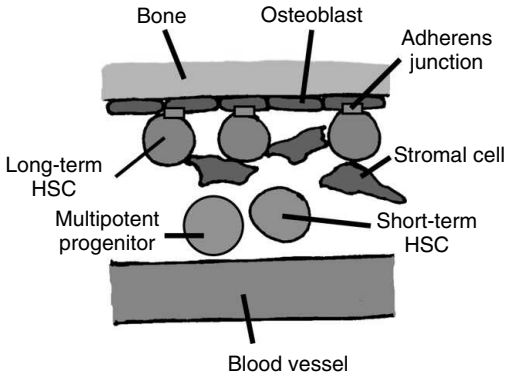

Fig. 4 Hematopoietic stem cells. Long-term hematopoietic stem cells (HSC), short-term HSCs, and multipotent progenitors reside in the bone marrow. Long-term HSCs are in close association with osteoblasts, present along the inner surface of the bone, and are surrounded by nearby stromal cells. Long-term HSC give rise to short-term HSC, which are analogous to transit amplifying cells. Short-term HSC have a limited self-renewal potential, and they generate multipotent progenitors that do not self-renew. Multipotent progenitors give rise to differentiated blood cells of the lymphoid and myeloid lineages.

BMP signaling in adult mice osteoblasts, by the conditional knockout of the BMP receptor type IA, results in a threefold increase in osteoblast number, presumably via reduced BMP-induced apoptosis. This increase in osteoblast number is accompanied by a twofold increase in HSC number, as demonstrated by functional transplantation assays, suggesting that BMP signaling controls the number of HSCs by limiting niche size.

Osteoblasts are a signaling center for HSCs. Transgenic mice expressing a constitutively active parathyroid hormone (PTH)/PTH-related protein receptor have increased numbers of osteoblasts producing elevated levels of the Notch ligand Jagged 1. In these transgenic mice, HSCs show high levels of Notch activation and are increased in numbers as well. These effects can be mimicked by treatment with PTH hormone. In culture, Jagged-1 activation of Notch results in increased progenitor activity, suggesting that the Notch pathway stimulates self-renewal and/or maintenance of multipotency.

Osteoblasts also express the ligand Angiopoietin-1 (Ang-1) that activates the receptor tyrosine kinase Tie2 on the surface of closely associated HSCs. Transplantation experiments in which levels of activity of Tie2 in HSCs are manipulated by Tie2 mutations or expression of Ang-1, demonstrate that increased Tie2 activity inhibits cell division and enhances adhesion of HSCs to bone. Tie2 signaling is thought to maintain long-term HSC self-renewing properties by inhibiting their proliferation, which is consistent with the fact that negative cell cycle regulators and polycomb group gene products such as Bmi-1 and Edr-1 may also be important regulators of HSC self-renewal.

Other signals are also important for the biology of HSCs. Their self-renewal depends on JAK2 signaling as well as activation of either c-kit (upon release of its ligand by the metalloprotease MMP9) or Flt-3. Shh is also thought to contribute to self-renewal of HSCs. Moreover, lipid modified Wnt molecules are expressed in bone marrow, and overexpression of activated β catenin, a downstream component of the Wnt signaling pathway, results in increased numbers of HSCs. Purified, lipid-modified Wnt molecules can also stimulate self-renewal of HSCs in culture. Conversely, overexpression of

axin, a negative regulator of Wnt signaling, results in inhibition of HSC proliferation and increased death. Cell death is thought to normally regulate the homeostasis of HSC, as supported by the fact that expression of bcl-2, a negative regulator of cell death, results in increased numbers of HSCs *in vivo*.

3 Embryonic Stem Cells

Between fertilization and implantation, the zygote will undergo many rounds of cell division to form an embryo containing three layers, namely, the trophectoderm, the primitive endoderm, and the inner cell mass (ICM) (Fig. 5). Embryonic tissues are exclusively derived from the ICM, whereas extraembryonic tissues arise from all three layers. The ICM cells, therefore, can undergo a great number of divisions and are pluripotent, giving rise to all tissues during embryonic development as they are exposed to the appropriate differentiation signals.

Remarkably, the ICM can be removed from early preimplantation mouse or human embryos and dissociate into what are called embryonic stem (ES) cells (Fig. 5). Under the appropriate signals, ES cells can be expanded in culture indefinitely (i.e. remain immortal), which is a unique property. For example, primary cultures of genetically normal skin fibroblasts can be established, but are short lived, whereas transformed cells are long lived and can be perpetually propagated in culture, but have many genetic aberrations.

ES cells also retain their pluripotency such that, if injected into a developing embryo, they can give rise to all different cell types and tissues. The ability to isolate and culture ES cells has revolutionized the use of mouse as a model system. Methodology was also developed for genetic modification of ES cells in culture that can be reintroduced into developing embryos. Because they can potentially contribute to any tissue in the animal, including the germline, this allowed the creation of genetically modified mouse strains, widely used in scientific research to study basic biological questions, to mimic and investigate human disease conditions, and to test drug targets.

ES cells can also be induced to differentiate into multiple cell types in culture. For instance, embryoid bodies containing

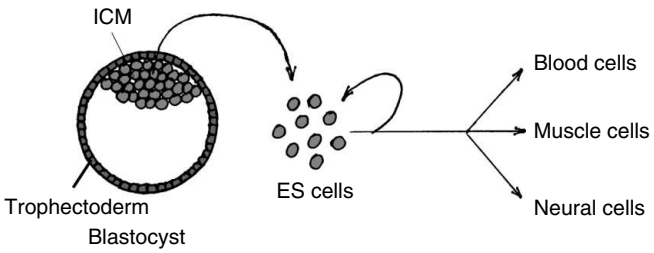

Fig. 5 Derivation of embryonic stem cells. Embryonic stem (ES) cells are derived from the inner cell mass (ICM) of the preimplantation embryo in the blastocyst stage. ES cells can be propagated in culture indefinitely as undifferentiated, pluripotent cells. If introduced back into embryos, ES cells can give rise to all cell types, and they can also be induced to differentiate in culture.

different embryonic tissues can form spontaneously if leukemia inhibitory factor (LIF) is removed. The ability to force ES cells to differentiate into embryoid bodies, or, in some cases, specific differentiated cells, has allowed the development of more cost-effective and faster assays for research, in addition to opening new avenues for the design of clinical approaches for tissue replacement and treatment of diseases. Mechanisms underlying directed differentiation of ES cells, however, are poorly understood.

Several intrinsic factors are known to be required for the extended life and pluripotency of ES cells, and these requirements reflect the natural embryonic environment from which these cells originate. Oct-4 is a transcription factor present in pluripotent cells, including the early preimplantation embryo (from which ES cells are derived), and primordial germ cells. It is essential for early embryonic development and becomes repressed during differentiation. Oct-4 requires cofactors such as the coactivator SOX2, and FGF4 and Hand1 are among its potential targets. The homeodomain-containing protein Nanog has a similar expression pattern to Oct-4, being expressed in preimplantation embryos (including ES cells) and primordial germ cells, and it is believed to be a pluripotency factor. A cluster of mouse ES cell-specific microRNAs, namely, miR-290, miR-291-as, miR-292-as, miR-293, miR-294, and miR-295 has recently been identified. The expression of these microRNAs is repressed during differentiation of ES cells into embryoid bodies, and they are also absent from adult mouse tissues. Similarly regulated microRNAs that are human ES cell-specific have also been identified, suggesting that mouse and human microRNAs may have a role in maintaining pluripotency of ES cells and regulating early embryonic development.

Recently, global gene-expression analyses of many human and mouse ES cell lines have been performed in an attempt to identify a pattern of gene expression that is common to all stem cells. Although these studies suggest that each ES line has a unique overall gene-expression profile, all ES lines were enriched for expression of Oct4 and Nanog. In addition, LeftyA and LeftyB, which encode members of the TGF-β superfamily, were also enriched in ES cells; further analysis will be required to establish whether they play a role in ES cell biology.

Extrinsic factors are also required for maintenance of ES cell properties. LIF is a cytokine that acts via the LIF receptor (LIFR) β coupled to the gp130 receptor, resulting in activation of the JAK-STAT pathway. Coupled with serum, LIF can stimulate long-term self-renewal of undifferentiated, Oct4-positive, mouse ES cells, but not human ES cells. In the absence of serum, cells undergo neural differentiation. Recently, BMPs 2 and 4 have been shown to promote self-renewal in combination with LIF, partially overcoming the serum requirement. BMPs act via activation of the Smad pathway and stimulation of Id proteins, which are negative bHLH factors that block neural differentiation.

As the regulation of ES cells is better understood, manipulation of ES cells will become technically less challenging and the balance between self-renewal and differentiation into specific paths more easily controllable to facilitate experimental as well as potentially clinical procedures. Importantly, given that differences are found between the regulation of mouse versus human ES cells in culture, it will be essential to carefully study human ES cell regulation and define optimal conditions for their

manipulation such that they can eventually be used for therapeutic purposes in the most effective and safe manner.

4
Themes of Stem Cell Regulation

Although no universally conserved signaling mechanism or intrinsic factor that controls stem cell identity and behavior has been found, common themes have emerged. For example, stem cells exist within specialized microenvironments where they are exposed to a unique combination of signals critical for regulating intrinsic factors to ensure their maintenance and proper division. The retention of stem cells within these niches is often achieved through the establishment of adherens junctions between niche cells and stem cells and/or via stem cell interactions with the extracellular matrix. Finally, stem cells are also subject to regulation by signals extrinsic to tissues in which they reside, such as hormones, nutrition, or physical insults.

4.1
Local Regulation – Stem Cell Niches

In 1978, Schofield first proposed on theoretical grounds the hypothesis that stem cells reside in specialized microenvironments, or niches, which generate an optimized set of signals that maintain stem cell properties. More recently, experimental data obtained from several different stem cell systems have demonstrated the existence of such niches and have begun to reveal their structural, organizational and mechanistic features that are essential for the maintenance and function of stem cells.

The details of how niches function vary from system to system; however, common themes exist (Fig. 6). Stem cells reside near a basal lamina with supporting cells forming the niche, such as Sertoli cells in the mammalian testis, hub cells in the Drosophila testis, cap cells and terminal filament cells in the Drosophila ovary, spindle-shaped osteoblasts in the bone marrow, and endothelial cells and astrocytes in the brain. Specialized junctions ensure the retention of stem cells within this niche. For instance, DE-cadherin- and β-catenin-containing adherens junctions are present between hub cells and GSCs in the Drosophila testis and between cap cells and GSCs in the Drosophila ovary, whereas N-cadherin- and β-catenin-containing adherens junctions occur between spindle-shaped osteoblasts and HSCs. In the cases of the mammalian gut crypt stem cells, epidermal stem cells, and GSCs in the mammalian testis, attachment to the basement membrane occurs via β1 integrins expressed on the stem cell surface.

Residence within niches endows stem cells with special properties due to their exclusive exposure to a unique combination of signals produced by niche cells. These signals activate evolutionarily conserved pathways that often operate, either similarly or in a distinct way, in multiple stem cell systems as illustrated by the BMP family of signaling molecules, which are part of the TGF β superfamily. BMP2 and 4 are required for self-renewal of ES cells via the stimulation of Id proteins, which are inhibitors of differentiation. Proliferation and maintenance of GSCs in the mammalian testis is stimulated by both BMP8B and Sertoli cell-secreted GDNF, which is a more distantly related TGF-β family member. Elevated levels of BMP signaling are also found in hair follicle

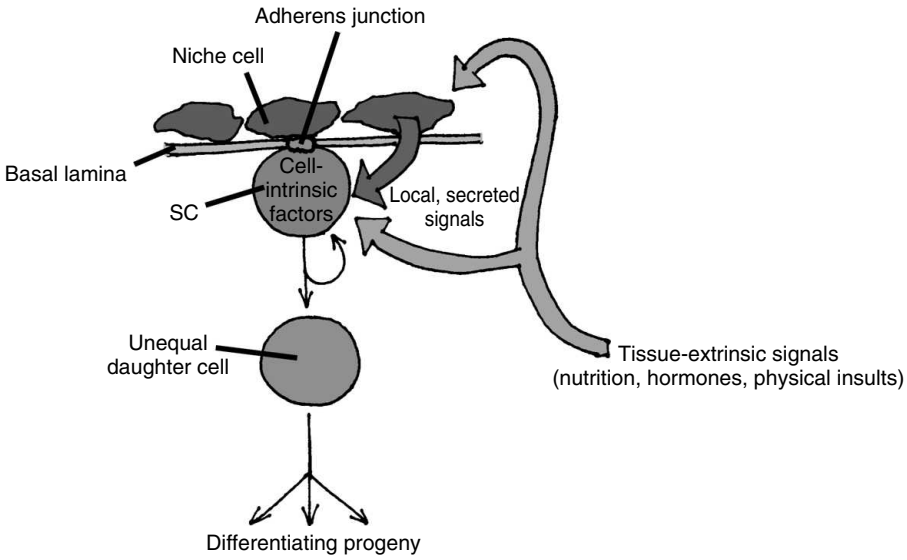

Fig. 6 Multilayered regulation of adult stem cells. Multiple intrinsic and extrinsic factors are required for the maintenance of stem cell (SC) properties and regulation of their function. Although the specific molecules may vary from system to system, common themes of SC regulation can be easily discerned. The local microenvironment (or niche) produces a set of signaling molecules that regulate SCs. SCs physically associate (for example, via adherens junctions) with cellular or extracellular components of the niche to ensure that they are permanently attached to and exposed to the unique signaling microenvironment that bestows them with SC properties. The locally secreted signals provided by the niche in turn regulate cell-intrinsic factors, which often represent global regulators of expression. The expression or silencing of specific intrinsic factors within SCs ensures that these cells keep their extended self-renewal capacity as well as their multipotency. The combined action of locally secreted and cell-intrinsic factors, therefore, ensures that SCs renew themselves and give rise to unequal daughter cells that differentiate into multiple cell types of a given tissue, ensuring the tissue's integrity and normal function. A tissue's need for new cells, however, is not always kept at steady state levels, and signals extrinsic to the tissue may change this demand. Such external signals may impinge on the normal regulation of SCs, either directly or via neighboring niche cells, to modify their rate of division and cell production. In addition, tissue-extrinsic signals may also modify the rate of division and death of the stem cell progeny.

bulge stem cells, as indicated by high levels of phosphorylated Smad2, and may also be important for NSC function. The BMP-like molecules Gbb and Dpp are produced by niche cells, and mediate GSC maintenance and proliferation in the Drosophila testis and ovary via inhibition of the Bam differentiation factor.

Other signals have important recurring roles in stem cell function. The LIF cytokine is essential for self-renewal of ES cells, an effect mediated via JAK-STAT activation, and JAK2 signaling is involved in regulating HSCs. The hub-produced Upd ligand also promotes GSC maintenance in the Drosophila testis via activation of the JAK-STAT pathway within these cells. The Notch signaling pathway is involved in maintenance of NSCs, HSCs, and GSCs within the distal end of the *C. elegans* gonad. The Hh pathway has conserved roles in stem cell function in

SSCs of the Drosophila ovary, NSCs in the mammalian brain, and HSCs. The Wnt pathway also has conserved roles in stem cell function. In the mammalian gut crypt, Wnt stimulates proliferation and inhibits differentiation of stem cells, and the Wg molecule plays a similar role in SSCs in the Drosophila ovary. In the mammalian hair follicle, Wnt signaling has a dual role, depending on the specific downstream effector. In bulge stem cells, increased Wnt signaling results in formation of a complex between stabilized β-catenin and Tcf3, a transcriptional repressor complex, whereas in the matrix, β-catenin and Lef1 form a transcriptional activator complex, resulting in distinct cellular behaviors. Multiple receptor tyrosine kinases also play roles in many stem cell systems.

4.2 Cell-intrinsic Factors

No specific and universal molecular marker for stem cells has been identified; however, several intrinsic factors have been shown to be required for stem cell maintenance and function (Fig. 6). The regulation of intrinsic factors by signals from the stem cell microenvironment provides a mechanism through which these signals control stem cell maintenance and function. These intrinsic factors are usually regulators of gene expression such as transcription factors or translational regulators, and the stem cell-related functions of some of these factors have been conserved across stem cell systems. For instance, the Oct-4 transcription factor is present in ES cells and undifferentiated spermatogonia in the mammalian testis, while Bmi-1 is involved in regulation of NSCs and HSCs. Upon activation of BMP signaling, the Mad/Med complex acts as a transcriptional repressor of the differentiation factor Bam in GSCs within Drosophila ovaries and testes. The translational inhibitors Nanos/NOS-3 and Pumilio/FBF-2 are important for GSC maintenance in Drosophila ovaries and *C. elegans* gonads. MicroRNAs are also emerging as intrinsic factors associated with mouse and human ES cells.

4.3 Tissue-extrinsic Factors

Despite the unquestionable importance of signals generated by the local stem cell environment in regulating stem cell properties and behavior, the activity of stem cells may also be influenced by stimuli originating outside the tissues in which they reside (Fig. 6). If a change in the demand for cells occurs because of external factors, such as, for instance, an injury or changes in nutrient levels, signals must be generated that are interpreted by stem cells, resulting in a change in their behavior.

Injury can have a dramatic effect on stem cell activity. Normally, skin homeostasis is maintained by the proliferation of stem cells within the basal layer of the epidermis, whereas hair follicle bulge stem cells generate daughter cells that migrate down to repopulate the matrix when signals from the dermal papilla are brought into close proximity because of the hair follicle cycle. In contrast, in severely burned patients who have lost the entire epidermis in large portions of their body, cells originating from the hair follicle can instead migrate up to reestablish the epidermis. Moreover, in mice carrying small area, full-thickness wounds, lineage tracing studies have demonstrated that bulge stem cells generate a large number of cells that migrate to the epidermis

to allow wound repair to take place. Similarly, brain injury (as well as mental and physical activity) results in increased neurogenesis in the dentate gyrus of the hippocampus. It remains unclear, however, what signals mediate a change in stem cell activity in response to physical stimuli in these systems.

Diet also has reported effects in several stem cell systems. Increased neurogenesis in response to caloric restriction has been reported in the dentate gyrus of the hippocampus of rats and mice, although this effect appears to be due to decreased death of newly produced cells rather than from increased proliferation. These effects appear to be partially mediated by brain-derived neurotrophic factor. Similarly, an increased number of long-term HSCs, as assessed by transplantation assays, have been reported in mice subjected to dietary restriction, although it is unclear how this effect is mediated or whether it occurs via modulation of cell death or proliferation.

The proliferation of stem cells can be controlled by nutritional status, as has been well documented in the Drosophila ovary for both germline and somatic stem cells. In females exposed to a high-protein diet, germline and somatic stem cells up-regulate their proliferation rates relative to those on a protein-poor diet in a coordinated fashion with their dividing progeny, and this process is reversible. In this case, similar levels of carbohydrates were provided to both groups of flies and they were, therefore, not under caloric restriction, which may explain the distinct effects of diet variations. The nutritional signal is relayed to the Drosophila ovary via insulin-like peptides, as demonstrated by a diminished response to nutritional status by mutants that are defective in insulin signaling. Parallels can be drawn to other systems. IGF-1 appears to stimulate HSC function as measured by transplantation assays. Mice in which diabetes is induced and which, therefore, have reduced levels of circulating insulin, show reduced levels of proliferation in the dentate gyrus subgranular zone. Furthermore, diabetes patients have reduced rates of wound healing, an effect that could be due in part to impaired stem cell behavior or proliferation.

Hormonal signals may also influence the activity of stem cells or differentiation of their progeny. In the bone marrow, PTH hormone appears to up-regulate the numbers of osteoblasts and the production of Jagged 1, thereby increasing long-term HSC numbers. In addition, growth hormone also promotes hematopoiesis via IGF-1 *in vivo*. Growth hormone also promotes higher rates of wound repair in patients with severe burns. Transgenic mice overexpressing growth hormone, however, show delayed and abnormal wound healing. In either case, it is unclear whether growth hormone exerts any direct effect on stem cells. In the mammalian testis, LH and FSH, produced in the pituitary gland, affect the local production of differentiation signals, although no direct effects on stem cells have been described. Administration of estrogen to diabetic mice restores proliferation in the dentate gyrus, suggesting that estrogens may normally play a role in NSC regulation.

Despite the many indications that tissue-extrinsic signals can modify stem cell activity, it is the least understood layer of regulation of stem cells. The identification of all extrinsic signals that modulate stem cells and elucidation of their mechanisms of action, which may involve directly signaling to stem cells or via their niches, remain areas of limited research and investment. A more complete understanding

of how external signals influence stem cell activity will be crucial, not only for establishing a thorough body of basic knowledge about stem cell regulation, but also to design better therapeutic approaches involving endogenous stem cells.

5 Implications

The study of stem cells in many diverse systems is the best approach for achieving a full understanding of their regulation. Many themes of stem cell regulation are conserved across tissues and organisms, and different systems offer distinct advantages, such as the detailed knowledge of the location of stem cell and niche components, a readily identifiable stem cell population, the availability of functional transplantation assays, the ability to monitor the behavior of individual stem cells *in vivo*, and/or the ability to recapitulate stem cell function *in vitro*. In recent years, immense progress has been made towards identifying stem cells and dissecting their regulation, and this work has broad implications for human health.

The study of normal stem cells has led to a revised model of cancer, in which a key event of tumorigenesis involves disruption of the regulation of stem cell self-renewal. In leukemias and solid tumors, only a small fraction of cancerous cells have extensive proliferative capacity that can give rise to new tumors, and these cells behave as hyperfunctioning stem cells. Indeed, several genes encoding proteins involved in the normal regulation of stem cells, such as Bmi-1, Notch, Wnt, and Hedgehog, are also involved in cancer formation. Thus, the knowledge obtained from further study of stem cell systems will likely continue to help elucidate the etiology of cancer.

Stem cells can also potentially be used therapeutically to replace damaged tissues in humans. This approach has been fairly successful for the replacement of long-term HSCs in cancer patients who have undergone high-dose chemotherapy. Bone marrow transplants containing stem cells can restore blood formation in patients and in lethally irradiated mice. The ability to enrich the population of cells introduced into patients or mice for HSCs on the basis of cell surface markers can greatly enhance the efficacy of this procedure such that approximately 200-fold fewer cells are needed. In addition, in cases of autologous bone marrow transplantation (i.e. when the bone marrow of a cancer patient is harvested prior to chemotherapy and later reintroduced into the patient to reestablish blood formation), the purification of HSCs away from potentially contaminating tumor cells can greatly enhance survival of the patients by reducing the recurrence of cancers. Likewise, therapeutic approaches using fetal tissues to replace damaged brain cells (e.g. dopaminergic neurons of Parkinson's disease patients) have been tried with limited success, underscoring the need for better knowledge of stem cell systems. Many other stem cell–based therapies are currently being developed; continued advancement in the stem cell field will be extremely valuable for their success.

Finally, the recent explosion in stem cell research has generated ethical debates. Some question the use of human embryonic stem cells in light of the fact that embryos are destroyed during the generation of ES cells and that other adult stem cell systems are available. Others argue that strict guidelines should indeed govern the generation and use of ES cells

(although not to the point of hindering research progress and its potential therapeutic benefits) and that, until effective stem cell-based therapies are available, all avenues of research involving embryonic and adult stem cells should be exploited.

Keywords

Chromatin Immunoprecipitation
A technique for identifying specific DNA sequences that are bound, *in vivo*, to proteins of interest.

Cloned Mice
Mice produced asexually from a single cell.

DNA Binding
Selective interaction with DNA.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Volume 12
Edited by Robert A. Meyers.

ISBN: 3-527-30649-8

Genomics
The systematic study of the complete DNA sequences (genome) of organisms.

High-throughput Techniques
Techniques that produce a large amount of data in a relatively short amount of time.

Proteomics
The systematic study of the complete complement of proteins (proteome) of organisms.

Transcription Factors
Proteins required to initiate or regulate transcription.

Transcriptional Complexes
Specific structures involved in transcribing the genome.

Transcriptional Regulation
Any process that modulates the frequency, rate, or extent of global transcription.

The regulome is defined as the complete set of regulons, where a regulon is the complete set of genes positively and negatively regulated by a specific regulatory protein. We propose the study of the regulome in mouse by analysis of 2500 known or predicted transcription factors, by generating one clone mouse with each TAP-tagged TF, followed by the study of the DNA binding sites of the TF by chromatin immunoprecipitation (ChIP) and the protein partners by proteomics, in several cellular types *in vitro*, and in different tissues and developmental stages *in vivo*. The integration of those data should provide the complete plan of mammalian transcriptional regulation.

1 Introduction

The completion of the human genome sequence is fundamental to paving the way for the complete understanding of human biology, but it is not the last step. The development of the concepts of transcriptome (the gene expression levels of all genes in the cell) and proteome (the concentrations of all proteins in the cell) were derived to define further layers that need to be described in order to explain a given cellular state. However, the mere description of the state of a cell does not explain how it works. A new layer integrating the levels of the genome, transcriptome, and proteome is needed to explain their interplay, which results in their dynamic change over time. This is the regulome, a concept coined in the year 2003 to describe the global set of regulatory molecular interactions that result in spatial–temporal variations of the cellular typology and state. The regulome includes the description of the interactions among genome, nucleotide and protein sequences, and metabolites,

occurring in different localizations of a cell, in different tissues, developmental stages, and possible states (e.g. normal versus pathological).

Ultimately, the description of the regulome of an organism would allow us to perfectly predict its transcriptome and proteome variation in different time periods, when the cellular initial state and the cellular environment are known. This accomplishment might be seen with skepticism today given the current state of the techniques and knowledge in molecular biology and notwithstanding possible limitations to the deterministic nature of the definition of regulome. However, the creation of the term regulome that, akin to those of transcriptome and proteome, is only putting preexisting concepts in a holistic perspective, is required by a technological revolution: the concept of regulome is born parallel to the possibility of technically measuring regulatory interactions at a genomic scale, the same way the concepts of transcriptome and proteome were born when high-throughput techniques to measure mRNA and protein concentrations were first possible. In this entry, we will describe our views about these developing techniques that will allow cellular regulatory relations to be measured at a scale that was never possible before. These new techniques will soon be modifying the way research is done in molecular biology the same way as proteomics and transcriptomics did in the 2000s, and genomics in the 1990s.

2 Definition

In prokaryotes, genes are organized and regulated in operons. Such structures do not exist in eukaryotes that rely on coregulation by the binding of thousands of transcription factors (TFs) to tens of thousands of binding sites in the genome. The complexity of transcriptional regulation grows in parallel with the complexity of the organism along with evolution. The more functions that have to be carried out, the more the elements that have to be controlled, that is, more compartments, developmental constraints, stem cells (tissue renewal and maintenance is necessary as the life cycle of the organism increases), interactions in a multicellular environment, and so on. All these elements appear as organism complexity increases from bacteria, to vertebrates, to mammals, and require a similar increment in the complexity of transcriptional regulation.

One of the main features of transcriptional regulation is the interaction of proteins (TFs) to DNA to regulate the transcription of nearby genes. Although it is possible to describe the patterns of the sequences to which TFs bind, it is obvious that we do not as yet understand the specificity of the interaction very well since such sequences exist often in high numbers all over the genome but, TFs do not bind everywhere. Recent experiments indicate that chromatin organization is dynamic and is subject to regulatory mechanisms that enforce the transcriptional potential of the genome during cellular commitment and differentiation. Chromatin is remodeled into transcriptionally permissive or repressive conformations by complexes that either covalently modify histones, or act in an ATP-dependent manner to reposition nucleosomes along DNA. Hence, chromatin structure restricts the availability of TF binding sites within different cell types at different developmental stages. Therefore, TF binding sites must be experimentally determined within each cell type rather than mapped using *in silico* analysis of genomic DNA sequence information.

Another element of transcriptional regulation is the interaction of TFs with other proteins in transcriptional complexes that modulate their actions. Therefore, understanding of the protein–protein interactions of TFs is also very important. Again, computational predictions of these interactions are not good enough and experimental analysis is needed.

Transcriptional regulation also involves other more indirect mechanisms, such as protein posttranslational modifications, small RNAs with capabilities of blocking or guiding the transport of coding mRNA, yet the most important point is controlling the production of mRNA from genes and also controlling which mRNA is produced (alternative splicing) (See Fig. 1). We think that the regulome can be described by analysis of just the TFs (as opposed to, for example, posttranslational modifications, or metabolites) because transcription is the hub through which all transcriptional regulation goes. Metabolites can be considered as effectors, and some proteins (such as receptors) as sensors of that process. Eventually, proteins are implied in those related processes and their production too is controlled by transcriptional regulation.

In this entry, we will present one proposal for studying the regulome. It is only one of many possibilities, and emanates from the thoughts revolving around the generation of the International Regulome Consortium (IRC), a liaison of research groups in Canada, UK, France, Singapore,

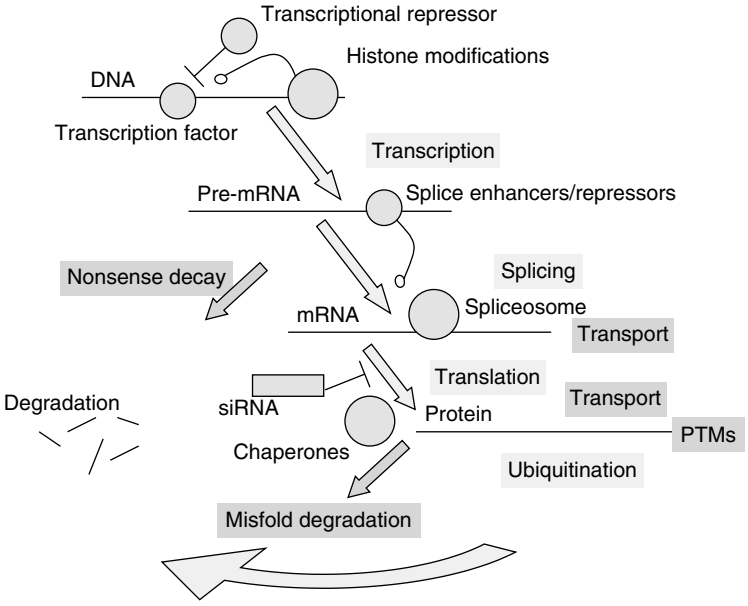

Fig. 1 The regulation of transcription is just one piece in the control of the expression of a genome in a phenotype, but it is situated right at the top of it. For example, posttranslational modifications of proteins control their function and cellular location, but those modifications are carried out by other proteins that are generated from genes ultimately controlled by TFs. We distinguish the control mechanism (transcription regulation) from its effectors (e.g. PTMs) or sensors (e.g. ion concentration).

and Australia, created in 2004 with the objective of joining efforts in the study of the regulome. For additional information concerning the mission and history of the IRC, please see the IRC Web portal http://www.internationalregulomeconsortium.ca/ and the IRC's 2004 white paper (http://www.internationalregulomeconsortium.ca/documents/IRC%20White%20Paper%20final%20V1.pdf).

3 Components

Although it is virtually impossible to check all possible conditions and combinations under which cells perform, and the system responding to them, a cell with its collection of biologically active macromolecules is finite. A number of measurements on the elements of the system with a large enough number of conditions should be enough to reveal their dependencies. The question is which of those molecules describe the regulome.

We propose to center the study on mouse as a model organism and on TFs. First, we have to define the genes that will be the object of the study. Since most genes, including all protein-coding genes, are transcribed by RNA polymerase II (RNAPII), the regulome can be defined by the RNAPII TFs that are expressed and the sites to which they bind in specific differentiated cell types and tissues.

There are a number of protein domains that have been seen as indicative of transcription factors, for example, DNA binding domains, but there are others too. Preliminary sequence analysis that was done by Timothy Hughes at the University of Toronto by scanning mouse genes for these protein domains against the Pfam and SMART databases of protein domains revealed more than 2200 mouse genes. Not all will be TFs but they give us a starting point.

We contrasted this list with microarray data from mouse cells displaying particularly rich patterns of expression: embryonic stem cells and their derivatives. Around 400 genes were not included in the set of genes detected by the microarray. Another 1000 were found to be expressed. Therefore, we estimated a number of 1400 targets.

How many binding sites are we considering? Any prediction will be an underestimation since it is not possible to discover absolutely all relevant binding sites in all possible conditions (e.g. pathological cases add further aberrant binding sites). However, to put our proposal in the context of current knowledge, we can carry out an estimation on the basis of well-known sets. For example, in a study of the evolution of TF binding sites, the number of binding sites described in the promoters of 50 genes is 186, so a guess of an average of 4 binding sites per gene looks reasonable. Given 30 000 genes in the mouse genome (another guess) we have 120 000 binding sites and possibly an average of 100 binding sites per TF. For a comparison, the current public version of the TRANSFAC database (16 Feb 2005, release 6.0) contains 911 mouse binding sites and 718 TFs, which is slightly above one binding site per TF.

How many transcriptional complexes are there? We examined the set of protein complexes in mouse annotated as DNA binding and implied in transcription in the BIND database of protein–protein interactions. Only 31 complexes are currently described (as of 16 Feb 2005) with a total of 103 partners. The average of subunits per complex is just above three. If we assume at least one complex per TF, it

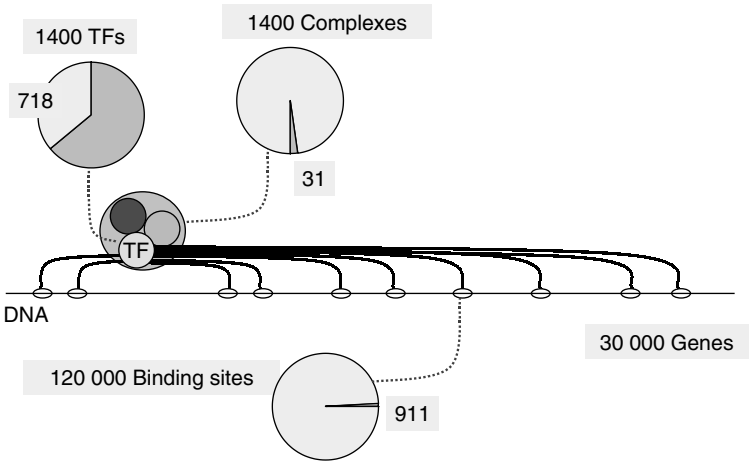

Fig. 2 Estimation of the amount of elements integrating the mouse regulome and of the fraction of those currently identified (darker sectors in pie charts).

means that we would be looking at 1400 protein complexes, describing about 4200 protein-to-protein interactions.

Additionally, in order to be able to have a good survey of TF modes of action and interactions, it is not realistic to scan for less than a hundred conditions (tissues, cells, developmental stages) per TF. Note that if we take TRANSFAC and BIND as a representation of the current knowledge of TFs in mouse, it means that only half of all TFs is characterized (718 of 1400), only 2% of the complexes they form (31 of 1400), and less than 1% of their binding sites (911 of 120 000). This indicates that there is a long way to go in the study of the regulome and, together with the need for testing hundreds of conditions, justifies a high-throughput analysis (see Fig. 2).

4 A Proposal for a High-throughput Analysis of the Regulome

Given a set of putative TFs in the mouse genome we propose to: create null mutations in all TFs in mouse embryonic stem cells (mESC) and characterize the phenotype and gene expression profile *in vivo* and *in vitro*; create mESC lines with dual ''knocked-in'' affinity tags at the C terminals of 1400 RNAPII TFs; affinity purify the tagged proteins from undifferentiated and differentiated mESC and various adult mouse tissues in which they are expressed; identify interacting proteins by SDS-PAGE, MALDI-TOF MS, and LC-MS/MS; and identify TF binding sites by chromatin immunoprecipitation (ChIP).

We propose to generate a clone mouse line for each of the 1400 target TFs. Each target gene will be inserted in a bacterial artificial chromosome (BAC) subsequently targeted in mESC. Hybrid mESC lines will be used to generate targeted clones. Use of hybrid mESC lines dramatically increases the frequency of survival to adulthood of mice generated by mESC-tetraploid embryo aggregation. Following excision of the selection cassette, the gene will be modified by the insertion of the tag. We propose the generation of mice for *in vivo* analyses,

using mESC-tetraploid embryo aggregation by fusion of two-cell-stage embryos and aggregation to targeted hybrid mESC following standard protocols. Embryos that develop into blastocysts are then transferred to the uterus of surrogate mothers and mice derived entirely from the targeted mESC are born 17 days later.

The association of TFs or TF complexes with DNA *in vivo* can be analyzed by using the ChIP procedure. Briefly, proteins are cross-linked to DNA by treating living cells with formaldehyde and then antibodies are used to precipitate specific proteins from sonicated chromatin preparations. In such experiments, specific genes or regions of genes that are coprecipitated with the protein are amplified and quantified by PCR. Depending on the number of PCRs, the approach can locate the binding site for a given factor on a given gene to within 50 bp or less.

TFs are regulated by forming part of transcriptional complexes with other proteins. For example, they may need to bind a protein in order to bind to DNA. Therefore, an important part of assessing the regulome is the elucidation of the protein partners of TFs. Of the many experimental methods that have been developed for the identification of protein–protein interactions, one of the most appropriate for systematic analysis involves expressing a tagged protein at its normal concentration *in vivo* so as to avoid nonphysiological interactions. This is used to retrieve and purify the complexes interacting with the tagged protein. Then, standard proteomic methods can be applied to detect the protein components of the complex. In particular, in the TAP method, two affinity tags, protein A from *Staphylococcus aureus* and a calmodulin-binding peptide (CBP) are placed at the C terminals of the proteins to be analyzed.

5 Computational Challenges

The approach presented here to the study of the regulome will produce details of the DNA binding sites and protein partners of thousands of TFs in a variety of cells and conditions. There are three major computational challenges posed by that data. The first two are the storage/dissemination of the data and the integration of the data with existing databases. These are the basis for the third and most important computational task, which is the translation of the data into predictions evaluated with a score indicating the confidence of the prediction. This requires the interpretation of the data produced above and to model the results according to a regulatory network. Such a step is necessary in order to suggest experiments to verify the most interesting predictions (according to their novelty, relevancy, or confidence).

6 Conclusions

The generation of data of complete regulomes of several organisms will happen in the following years. This is likely to be the next biological data revolution, which is more experimentally complex to obtain than sequencing, or measuring mRNA levels by DNA microarrays, but also richer in content.

The total knowledge of a biological entity brings an increase in the possibilities for the use of that information that is orders of magnitude richer than a partial or even nearly complete knowledge of that entity. This is seen with the sequencing of complete genomes, which allows the knowledge of complete sets of genes in

bacterial organisms and to elaborate complex inferences about their metabolism, even in the absolute absence of any experimental characterization on any protein of that organism. Identically, the knowledge of the regulome in a number of organisms will result in the complete understanding of the cellular control, including maintenance, development, and the origin of pathologic states.

The complete knowledge of the regulome will unleash the next data revolution. This will probably be the use of dynamic models of complete eukaryotic cells that now must work on partial knowledge of the regulatory network and therefore with a very limited predictive power. This is a necessary step before the modeling of multicellular ensembles, and the modeling of tissue differentiation, stem cell, and cancer-related processes at cellular scales.

The data obtained on the regulome rely on many pieces of information that are prone to change over time, such as methods of data interpretation using databases and those databases themselves. This requires the storage of the data and its analysis in a dynamic form in yet another database in which the data is not just collected but continuously reevaluated, as databases and methods improve over time. The challenge is to convince molecular biologists to get used to looking at data in these repositories, and to display the data in ways that make it easy for them to understand the data and get insights for the design of relevant experiments. In this way, we can expect that the study of the regulome will stimulate fundamental and translational research and provide new insights in understanding the genomics of cell function that are critical for developing novel therapies that pave the way to improved health benefits for society.

Keywords

DNA-damaging Agents
Physical or chemical agents, for example, such as Xrays or aflatoxin B_1, which affect DNA functions by distorting its structure. The newly formed structure is often termed *DNA lesion*, which often precedes the appearance of a mutation. Note that the transmogrification of a DNA lesion may give rise to a mutation. Yet, note that a lesion is not a mutation.

DNA Repair
A collective term that encompasses at least three dozens of biochemical processes that are involved in restoring the structure of DNA after it has sustained damage.

Gene
A segment of DNA, the expression of which results in the production of a messenger RNA (mRNA) that translates into a protein.

Genetic
Qualifies what pertains to DNA, whereas, *hereditary* specifies a trait passed from a parent to its progeny. The Down syndrome is a genetic disease, resulting from a triplication of human chromosome 21. In contrast, mucoviscidosis is a hereditary disease caused by a mutation located in human chromosome 7.

Genome
Designates the whole set of chromosomes present in a cell.

Mutagens
Physical or chemical agents that alter DNA, increasing the occurrence of mutations.

Mutagenesis
Designates the overall process that results in the induction of a mutation.

Mutation
A DNA change that is recorded durably and passed on to the offspring. *Induced mutations* result from the error-prone repair of DNA lesions or from DNA replication errors. *Spontaneous mutations* correspond to naturally occurring DNA changes.

SOS Mutagenic Repair
In prokaryotes, it is an induced error-prone DNA replication, involving a specialized polymerase that causes the synthesis of a base across a lesion (termed TLS, standing for trans-lesion DNA synthesis). TLS is a major SOS function regulated by the activation of RecA protein.

During their lifetime, all the cells of a living organism are exposed constantly to harmful agents such as radiations and chemicals. DNA (deoxyribonucleic acid), a crucial cell constituent, is highly sensitive to deleterious agents. A large majority of cells survive when exposed chronically at low doses since DNA damage induces cell enzymes that repair DNA lesions. Repair acts very efficiently when DNA stops replicating after the occurrence of lesions. After repair has taken place, DNA replication resumes, followed by cell division. While various repair processes concur to restore cell survival, each of them is never completely efficient and lesions remain in the DNA, acting as stepping-stones. Resumption of DNA synthesis on the strand opposite the remaining lesions permits the bypassing of these obstacles. A process, called *trans-lesion DNA synthesis* is one of the most efficient processes generating mutations. Mutations come into view in cells that survive the DNA-damaging treatment.

In short, a mutation is a DNA change that is recorded durably and passed on to the offspring after replication. A number of mutations in *germ* cells have *harmful* effects for they often cause hereditary diseases. Similarly, mutations that accumulate in dividing body cells (*somatic cells*) can generate cancers. Yet, most of the occurring mutations behave as *neutral* in their usual environment. Selection forces the genome to retain the *beneficial* mutations.

1 The Structure of DNA Determines its Functions in Repair and Mutagenesis

DNA is the essential component of chromosomes in all cells. Each chromosome is made of an extremely long DNA molecule with two intertwined *complementary strands* (a double helix). Each strand consists of a poly(phosphate sugar) backbone from which project Adenine (A), Cytosine (C), Guanine (G), and Thymine (T) bases at each sugar. The two strands form a *duplex* maintained by hydrogen bonds between complementary bases: A binds to T and G to C. The four bases A, C, G, or T may combine into a linear chain that constitutes a *genetic sequence* (see Fig. 1).

DNA of the whole set of chromosomes in a cell is called the *genome*. A bacterium like *Escherichia coli*, a natural resident of the colon of mammals, is made of one chromosome, whereas human cells carry 23 chromosome pairs. In general, the cells of complex organisms like mammals have more chromosomes per cell than lower organisms like microbes.

The double-stranded structure of DNA permits its duplication, one strand providing the template for the making of its copy. Not only has such a structure the possibility of replicating but also of repairing itself. If, for example, ultraviolet light hits a strand of the DNA double helix, the damaged piece undergoes: (1) excision of the damaged DNA piece that leaves a gap; and (2) DNA resynthesis to close the gap, using the undamaged strand as a template to make a correct new strand.

Repair processes are many, involving more than fifty identified proteins. The three major processes that repair DNA are (1) *excision*; (2) *recombination*; and (3) *mismatch repair*.

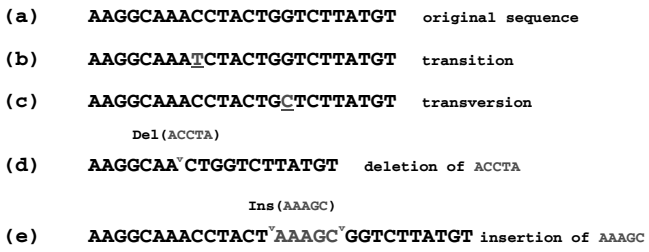

Fig. 1 Types of mutations: (a) wild type original sequence; (b) transition from C to **T** (underlined bold T); (c) transversion from G to **C** (underlined bold C); (d) deletion (Del) of the sequence **ACCTA**, the ^{V} sign indicates from where it has been taken out; and (e) insertion (Ins) of the sequence **AAAGC**, the two ^{V} signs indicate where the sequence has been put in.

There are two types of excision repair depending on the length of excised DNA: nucleotide excision repair (NER) or base excision repair (BER). Various different types of recombination repair exist depending on whether the recombining DNAs are *homologous, nonhomologous*, or *nonhomologous end joining*. More complicated repair processes use a combination of all of these. Repair, by definition, should lead to the full restoration of the original DNA structure. In fact, almost all repair processes leave a low percentage of errors, some of which give rise to mutations.

The main function of DNA is to code for the hereditary traits that are passed from parents to progeny. Recently, geneticists have identified the long string of bases present in many genomes, from bacteria to man. The mapping of the human genome has resulted in building a compendium of the number and positioning of the 7000 or so genes, whose mutations are responsible for human hereditary diseases.

When a mutation occurs within a gene, the protein encoded by the gene is often altered (see Figs. 1b, c and 2c); this alteration may produce a visible change (*phenotype*) of the organism under study. The actual mutation itself (*genotype)* is invisible to the naked eye, whereas the technique of DNA sequencing will locate it precisely.

Since a mutation is a DNA change, one should define it in relation to a preceding, parental DNA sequence (Fig. 1a). Consequently, geneticists have agreed to define a *standard genetic sequence* for each organism studied. The adopted standard is usually the most widespread type that fits in its environment.

Mutations fall into three classes termed *deleterious, neutral*, or *beneficial* according to their effects on the organism in which they arose. These qualifications are only valid in relation to a given environment.

1.1 When Donated by Both Parents, the CFTR Mutations are Deleterious

Human cells carry 22 pairs of chromosomes called *autosomes* plus a pair of sex chromosomes. The probability for a child to suffer from *cystic fibrosis* is one out of 1600 children. This disease is dramatic; the fluidity of lung secretions disappear, stifling normal pulmonary aeration. The cause of the disease is genetic: the affected child has received from the two

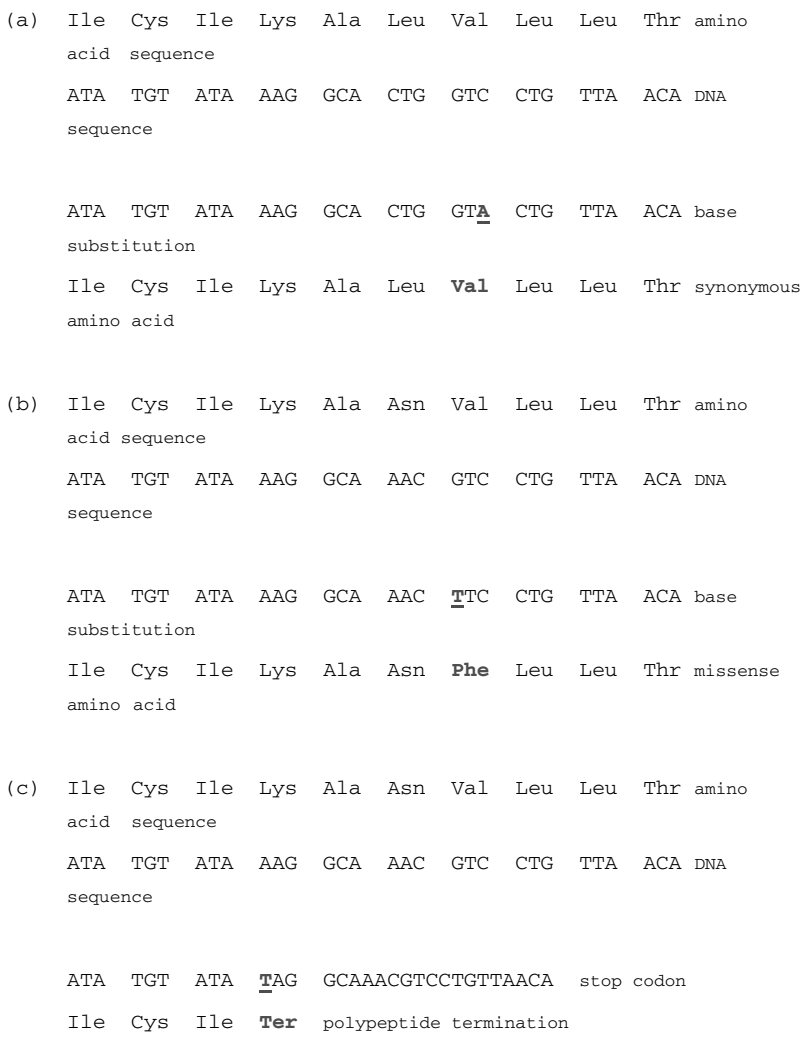

Fig. 2 Types of substitutions in a protein-coding region: (a) synonymous, (b) missense, and (c) nonsense. In each case, the top sequence is wild type while the bottom sequence is the mutated one.

parental chromosomes 7, a mutated cystic fibrosis CFTR gene. In Europe, the frequency of people carrying only one CFTR mutation is 1/40. Such heterozygotes show a decrease in the fluidity of mucus excretion that may pass unnoticed. Geneticists have postulated that the selection of one CFTR mutation results from past cholera epidemics. People, ill with cholera, suffer from an almost 15 L of diarrhea per day; they mostly die of dehydration more than from infection sickness. Individuals with only one mutated cystic fibrosis CFTR mutation leak much less water and can overcome the infection with cholera germs. In countries where

cholera is endemic, individuals with only one CFTR mutation seem to be resistant to cholera.

The probability for a child to receive two CFTR mutations is 1/1600. This fraction shows the high frequency of cystic fibrosis in the human population. Resistance to cholera in a human population is proportional to the frequency of occurrence of spontaneous CFTR mutations.

2 DNA-damaging Agents are Mutagens

Naturally, mutations arise at low frequency. To increase the frequency of appearance of mutations, Herman Muller thought of irradiating Drosophila eggs with X rays. He discovered that X rays increased the mutation frequency as a function of the absorbed dose. Moreover, chemicals such as mustard gas (yperite) showed a similar dose response. Agents that produce mutations are denoted *mutagens*.

2.1 A DNA Lesion is Different from a Mutation

The practical knowledge of DNA lesions that we have is that after too much bathing in the sun, our skin becomes red and itching. Solar radiations, named UVA (320–400 nm), produce various *DNA lesions* within our skin cells. Photobiologists have identified more than 20 lesions, depending on their 3D-structure and shapes.

Why is it that with so many diverse lesions produced, we observe that 85% of them are single base pair changes, in just a DNA base? For example, Adenine (A) may change into Cytosine (C), Guanine (G), or Thymine (T). Benzopyrene, a chemical inhaled with tobacco smoke, when metabolized, gives rise to a chemical derivative, benzopyrene dihydrodiol that sticks to DNA. In our body, this compound produces a single base mutation: an A or a T or a C or a G.

What is the relationship between a DNA lesion and a mutation? In the preceding example, a benzopyrene-dihydrodiol-base complex bound to one DNA strand is taken out by excision, which leaves a gap of around 10 bases (in bacteria) or 30 bases (in human cells). DNA resynthesis will fill the gap, sometimes in an error-prone way, giving rise to a mutation. Recall that a DNA lesion is not a mutation even if nowadays one can synthesize a piece of DNA with an altered base *in vitro*.

Biochemical reactions, namely, *trans-lesion DNA-synthesis*, proceed on the DNA to restore a functional sequence at the site where there was a lesion. Most unexcised DNA lesions block DNA replication. SOS-induced-repair polymerases bypass the DNA lesions, allowing the cells to survive. At least 50 repair proteins concur to cell survival. Repair enzymes act all the more efficiently as DNA lesions are not too many.

Interestingly, the lesions that trigger an SOS response in bacteria induce a cascade of repair processes. Structural restoration of a DNA double helix is a primordial step permitting replication, cell division, and cell survival to take place.

3 Characteristic Mutation Types

By the use of various techniques, biologists proved that all living species possess a similar DNA structure. In all genomes, there are four nucleic bases, A, C, G, T, whether in microorganisms or mammals.

1. *Point mutations*: The most frequent are base substitutions. Substitutions

happen between purines, Adenine (A) and Guanine (G), or between pyrimidines, Cytosine (C) and Thymine (T) (Fig. 1b); they are called transitions (A capital letter for each base name is used to stress what base the symbol stands for). An AT base pair may give rise to a GC (AT → GC) and, conversely, a GC base pair to an AT (GC → AT); the two-way reactions are illustrated as AT ↔ GC.

Transversions are substitutions of a purine for a pyrimidine and *vice versa* (Fig. 1c). There are four reciprocal base pair changes: AT ↔ CG; AT ↔ TA; GC ↔ TA; GC ↔ CG. Base substitutions that occur in protein-coding regions affect the structure of the expressed protein with the exception of the third base of a codon when the change does not modify the amino acid (see neutral or synonymous mutation, Fig. 2a).

2. *Deletions and insertions*: Examples of deletions and insertions are seen in Fig. 1(d) and (e). Note that an unequal crossing-over between two chromosomes may result in a deletion of a DNA segment in one chromosome and in an addition in the other.
3. *Frameshifts*: A small deletion or insertion within a gene, whose number of bases is not a multiple of three, causes a shift in the reading frame, denoted frameshift (Fig. 3a). Then, the coding sequence downstream displays a wrong phase. The new phasing changes the nature of the encoded amino acids; or else a new stop codon may be brought upstream into phase, producing a shortened protein. Figure 3(a) shows a protein sequence that may not have normal activity. Figure 3(b) also illustrates the fact that an addition of a base results into a +1 frameshift that may remove a preexisting stop signal giving rise to an elongated protein.
4. *DNA rearrangements*: Deletions of a segment of a gene or of sets of genes may reduce or eliminate protein functions

Fig. 3 Examples of frameshifts caused by deletion or insertion. (a) A deletion of a G causing premature termination. (b) An insertion of a G obliterates a stop codon. Termination codons are underlined. In each case, the top sequence is wild type while the bottom sequence is the mutated one.

(Fig. 3). In addition, insertions of large DNA segments can occur, as can duplications, inversions, and other more complicated DNA rearrangements. All these processes are the likely results of recombination between DNA sequences sharing homology. Agents that break chromosomes like X rays or yperite, facilitate DNA rearrangements.

Effect of a Bcl2 rearrangement: When a piece of human chromosome 14, carrying the *Bcl2* gene, and thus expressing a function preventing cell death, is translocated to chromosome 18, then the *Bcl2* gene gets expressed constantly. This leads to the production of a modified immunoglobulin, normally eliminated from the body by cell death. The modified immunoglobulin is kept alive here because of the *Bcl2* translocation. Thus, a pool of unhealthy cells builds gradually; point mutations accumulate in those unhealthy cells and will eventually give rise to cancer cells.

5. *Insertion of transposable genetic elements*: Transposable genetic elements, also called transposons or jumping genes, are present in most organisms. They are highly mobile around chromosomes. If a transposon inserts into a gene encoding a protein, it may cut the gene into two pieces and the protein may not be expressed as a whole. This is the negative property of transposon insertion. On the contrary, if a transposon with active promoters inserts itself into the regulatory region of a gene, it may strongly increase the expression of downstream genes.
6. *Mutation reversions: true- or pseudoreversion of a mutation*: Sometimes after a few generations, the phenotype of a mutant organism seems to have reversed to the wild type original and a question arises whether the mutation reverted to the original parental type? Or else, has the mutation remained in the DNA while another mutation had occurred elsewhere, counterbalancing the first one?
7. *Mutation hotspots*: Mutations may occur at random along the genome, but more often than not, they crop up at some sites designated hotspots. There is such a hotspot in the *E. coli* chromosome: the dinucleotide CpG, in which one finds the cytosine frequently methylated, changes to TpG, introducing an error.

   Another specific mechanism can take place, designated *induced activation of cytosine deaminase* (AID). The deamination of methyl cytosine gives rise to thymine in the absence of replication. This process converts cytosine to uracil and adenine to hypoxanthine. It may be the main cause of immunoglobin hypermutation, which may result from the conversion of cytosine to uracil with the AID enzyme.

   The dinucleotide TpT is a mutation hotspot in prokaryotes (but not in eukaryotes). The particular 3-D shape of a DNA region generates some targets for specific enzymes like methylases. In bacteria, DNA regions containing short *palindromes* like 5′GCCGGC3′, 5′GGCGCC3′, and 5′GGGCCC3′ are prone to mutate more frequently than other regions. In eukaryotic genomes, short tandem repeats, resulting from *slipped-strand mispairing* are often hotspots (Fig. 4a,b).
8. *Mutations at regulatory sequences*: DNA encodes sequences that control the expression of proteins, such as promoters

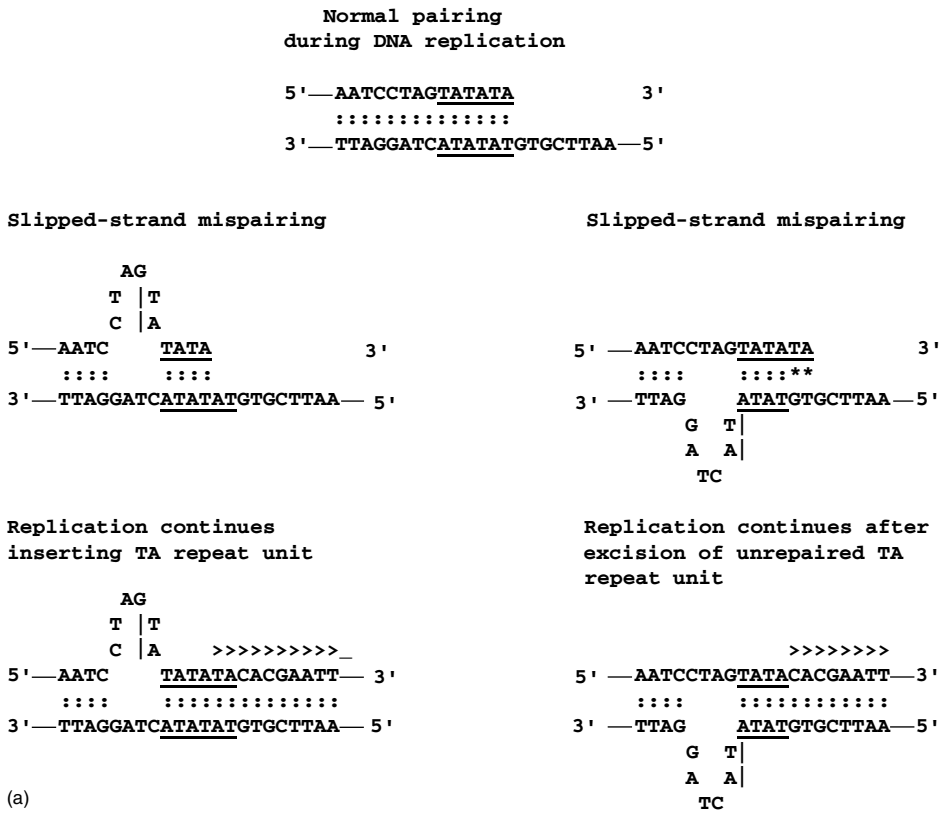

Fig. 4 Generation of duplications or deletions by slipped-strand mispairing between contiguous repeats (underlined). Small arrows indicate the direction of DNA synthesis. Dots indicate base pairing. (a) *A two-base slippage in a TA repeat during DNA replication*. Slippage in the 3′ → 5′ direction results in the insertion of one TA unit (left panel). Slippage in the other direction results in the deletion of one repeat unit (right panel). The deletion shown in the right panel results from excision of the unpaired repeat unit (asterisks) at the 3′ end of the growing strands, presumably by the 3′ → 5′ exonuclease activity of DNA polymerase. (b) *A two-base slippage in a TA repeat in nonreplicating DNA*. Mismatched regions form single-stranded loops, which may be targets of excision or mismatch repair. The outcome (a deletion or an insertion) will depend on which strand is excised or repaired and which strand is used as template in the DNA repair process. (Modified scheme from Levinson and Gutman).

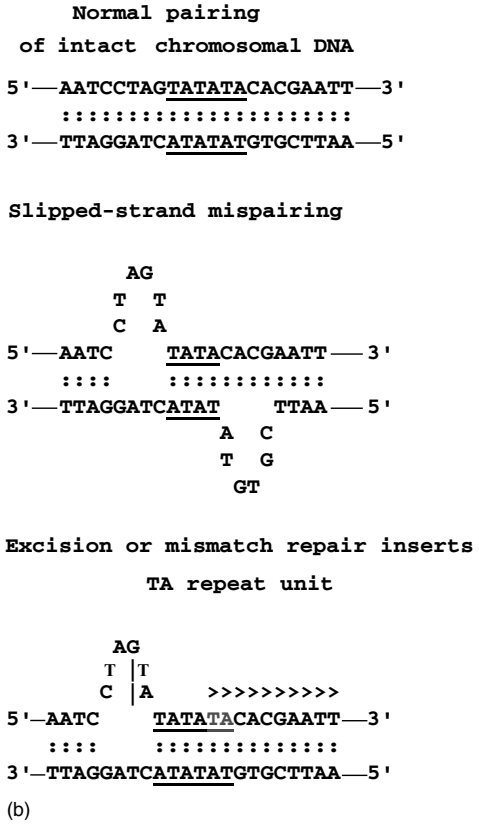
and operators. Mutations in these sequences may alter the cell concentration of proteins encoded downstream of the regulatory sequence. Overexpression or underexpression of proteins may sharply modify the function of a gene in an organism. Since many proteins work in a concerted action, a sharp increase or decrease in the cell concentration of a protein may disturb the very existence of an organism.

4 Silent Base Substitutions

A mutation that does not cause any amino acid change in the expressed protein is

Fig. 4 (*Continued*)



(b)

dubbed *synonymous* and may become *silent*. In Fig. 2(a), the protein codes for the valine amino acid but the DNA sequence reveals a base change.

A *nonsynonymous* mutation alters an amino acid, resulting in a *missense* or a *nonsense* mutation. A missense mutation specifies an amino acid different from the one originally encoded, for instance, valine (Val) becomes phenylalanine (Phe) (Fig. 2b). A nonsense mutation changes a codon into one of the three termination codons TAG, TAA, or TGA. Then, a truncated protein is produced since lysine (Lys) becomes Stop (Fig. 2c).

4.1 Synonymous Mutations are Neutral

In a DNA sequence that codes for a protein, each of the sense codons can mutate to nine other codons by means of a single base substitution. For example, the triplet CCU that codes for proline (Pro) can give rise to three *synonymous* substitutions CCC, CCA, or CCG, which also code for proline (Pro). In a different order, the triplet can give rise to six *nonsynonymous* substitutions, which code for different amino acids, UCU for serine (Ser), ACU for threonine (Thr), GCU for alanine (Ala), CUU for leucine (Leu), CAU for histidine (His), or CGU for arginine (Arg).

Since the genetic code defines 61 sense codons, it is reckoned that the possible codon substitutions are $61 \times 9 = 549$. If we assume that base substitutions may occur at random and that all codons are equally frequent in regions coding for proteins, we can compute the expected proportion of the different types of base substitutions. Because of the structure of the genetic code, *synonymous* substitutions occur mainly at the *third* position of codons. Indeed, 69% of all the possible *synonymous* changes in a codon are at the third-base position.

In contrast, substitutions at the *second* position of codons are *nonsynonymous*, and so are the vast majority of base changes at the *first* position (96%).

Synonymous amino acid replacements do not alter either protein structure or function. From an evolutionary viewpoint, these mutations are *neutral* since they do not seem to affect the physiology of the mutated organisms. Such synonymous mutations accumulate with time since there is no counterselection for their emergence. Synonymous mutations indeed generate *change at the DNA level*, as indicated by the use of restriction enzymes and sequencing techniques. Over time, accumulation of synonymous mutations increases DNA divergence between individuals within a species. Then, a new species can emerge by segregation. Chimpanzee and man share 98.5% of the structure of their proteins. DNA sequences in the two species have diverged upon evolution from a common ancestor. The consequence of the divergence is a gradual loss of DNA homology that hinders recombination between the two species and thus the formation of hybrids.

A species is defined by the property of the individuals within a group to mate and give rise to a progeny since the parental DNAs can recombine. They can do so if, and only if, the DNAs are homologous. If genomic DNA accumulates third-base changes with time, the DNA of the mating pair turns out to be too divergent with respect to their respective ancestors. The resulting diverged individuals may attempt to mate, but they cannot give rise to progeny.

Since the act of mating is followed by DNA recombination, the latter is successful only if it arises between two homologous DNAs. Mating is doomed to fail if it occurs between two heterologous DNAs. The first step in recombination is the pairing of two pairs of DNA strands. When two heterologous DNA chains attempt to pair, base-to-base *mismatches* arise between bases that should otherwise complement. Mismatches are removed by the induction of a very efficient repair process called *mismatch repair*. Radman and associates have demonstrated that recombination between two heterologous DNAs aborts through the action of *mismatch repair*.

5
Four Main Mechanisms that Generate Spontaneous Mutations

Spontaneous mutations may result from four main mechanisms: (1) DNA polymerization errors, (2) spontaneous oxidative DNA damage, (3) loss of a purine base, or less frequently, loss of a pyrimidine base, and (4) deamination of cytosine or of adenine.

1. *DNA polymerization errors*: Point mutations, usually transitions, arise from two successive faulty processes: (1) an error in chromosome replication resulting in a mismatch; and (2) followed with inefficient repair.

For example, DNA polymerase III may incorporate *in vitro* an incorrect base at a frequency of 10^{-6} to 10^{-7} per base pair per cell per generation. In *E. coli* bacteria, mismatch repair will remove the incorrect base, reducing the overall rate of replication and postreplication errors down from 10^{-9} to 10^{-10} per base pair per cell per generation.

Replication slippage, also denoted *slipped-strand mispairing*, is the major mechanism that accounts for frameshift mutations occurring at contiguous short repeats (Fig. 4).

2. *Incorporation of an oxidized base*: Exposed to oxygen, guanine is subject to oxidation that produces 8-oxo-G. This abnormal base has a tendency to slip into DNA, generating transversions. Fortunately, an elaborate repair system comes into play that either removes 8-oxo-G or decreases the consequences of its incorporation. Such a repair system is ubiquitous, protecting DNA from oxidative lesions.

   Note that the oxygen we breathe is far from harmless. Oxygen is a DNA-damaging agent and may have a role in the aging process. Ames and associates have correlated the number of oxidative hits to DNA with the amount of DNA breakdown products released in rat urine and human urine. They have shown that the number of oxidative hits to DNA per cell per day is around 100 000 in rats and about 10 000 in humans. The 10-fold difference may result in part from the elevated metabolic rate of rodents, at least five times higher than that of mammals.

   The mutagenic action of 8-oxo-G implies that there is no clear-cut difference between ''natural'' and ''artificial'' DNA-damaging agents. The distinction between spontaneous and induced mutations is also vague since the air we breathe does also insert oxides into DNA.
3. *Loss of a nucleic base*: It is the most frequently arising spontaneous lesion. If the chemical bond between sugar and base breaks, releasing a free base and leaving a gap in the sequence of bases, such an event generates an abasic site (apurinic or apyrimidinic). Loss of a purine base is more frequent than loss of a pyrimidine. A pyrimidine base strengthens DNA, which is in general sturdier than RNA.

   Replication over an abasic site may produce a point mutation since the polymerase has no way of determining the identity of the missing base it has to copy. Adenine (A) seems frequently placed opposite the missing base. When T is the missing base, the placement of an A restores the normal coding.
4. *Deamination*: This process may convert cytosine to uracil and adenine to hypoxanthine. The former conversion seems to be involved as the main cause of immunoglobin hypermutation. This process would account for the creation of half a million antibodies, a process permitting our immunity repertoire to be constituted.

6 Induced Mutations

They may result from three different mechanisms: (1) the replacement of a base in the DNA by a base analog that confuses the polymerase; (2) an imperfect fit between a chemically altered base with another base during replication; and (3) the replacement of a base with a gap that lacks coding information.

1. *Base replacement by a base analog*: 2-Aminopurine, a base analog that mimics a normal base, causes frequent mispairing when incorporated into DNA.
2. *Mispairing by alkylation of bases*: Alkylation with ethylmethanesulfonate or with MNNG (*N*-methyl-*N*′-nitro-*N*-nitrosoguanidine) causes mispairing. Although these two chemicals modify different bases at various positions, alkylation at the O^6 position of guanine and at the O^4 position of thymine causes specific mispairing with T and with G, leading to GC ↔ AT and AT ↔ GC transitions. *In vivo*, O^6-alkylguanine and O^4-alkylthymine are two chemicals that cause the most mutations through alkylation.
3. *Noncoding lesions*: Ultraviolet light C (256 nm) generates pyrimidine dimers and 6–4 pyrimidine-pyrimidone compounds in DNA. Such lesions sharply bend DNA, distorting the precise pairing of bases upon replication.

7
Mutagenesis in Bacteria and Carcinogenesis in Mammals

Bruce Ames asked an interesting question: do mutagens cause cancer? If they do, it should be possible practically to replace the usual lengthy cancer tests on mice, lasting months and years, with a much shorter test involving bacteria instead of animals. Ames and collaborators devised a mutagenicity test using a *Salmonella* tester strain (*his*$^-$) that requires histidine for growth. The *his*$^-$ tester bacteria treated with various carcinogens produced *his*$^+$ mutants that were able to grow on a medium devoid of histidine.

To make the test even more efficient, the bacterial tester strains were engineered in order to: (1) prevent the removal of the DNA lesions produced by the chemical tested; (2) increase the mutagenic rate by introducing a mutator plasmid in the tester strains; and (3) render the tester strains permeable to chemical compounds in changing its cell wall structure.

In the experimental procedure, one mixes the chemical with rat liver enzymes to reproduce the metabolization of the compound by a human liver. In the test, a transient physiological chimera combines rat enzymes with permeable bacteria to reproduce the human situation.

The results of the tests have shown that more than 65% of the 3000 chemical compounds tested, which are rodent carcinogens also cause mutations in bacteria. The converse is true: most mutagens are active carcinogens. Using a bacterial test to detect potential carcinogens has saved time, money, and animal suffering.

Note that even though bacteria are evolutionarily distant from rodents and humans, they provide an excellent tool for establishing that mutagenicity correlates with carcinogenicity. This is because DNA damage is the origin of both processes.

Because the *Salmonella* mutagenicity test is rapid, accurate, and relatively simple, many government agencies and biological laboratories have tested new chemicals for their mutagenicity and their potential carcinogenicity all over the world. In the European Union, the bacterial mutagenicity test has become mandatory. The overall result is that even though bacteria are evolutionarily more than a billion years distant from rodents and humans, they provide an excellent tool for measuring the mutagenic potential of chemical compounds. Government agencies and biological laboratories are testing newly found chemicals for their mutagenicity and potential carcinogenicity

all over the world. In the European Union, the *Salmonella* mutagenicity test has become mandatory.

8
Carcinogens Leave No Definite Mutational Signatures on DNA

In human cells, a gene called *p53* expresses a protein that inhibits the occurrence of cancers; wild type protein P53 looks as an *anti-oncogene*. Measurements of the occurrence of p53 gene mutations demonstrated that in more than half of all cancers taken together, 90% of the p53 mutations are point mutations, two-third of them being transitions GC → AT.

In bronchial cancers, one finds that 45% of p53 mutations are transversions GC → TA. Benzopyrene, a mutagen produced by cigarettes or car exhausts, gives rise to a low level of GC → TA transversions.

Is the presence in cancer cells of a GC → TA transversion in the *p53* gene a case for making benzopyrene responsible for the production of the mutation? So many carcinogens and environmental pollutants are causing GC → TA transversions. How is it possible to incriminate benzopyrene itself in causing a tumor? Moreover, a point mutation is so common and so minute a DNA change that it is hard to take it as an indelible mark left over by a carcinogen.

In order to provide a legal proof for carcinogenicity of a mutated DNA sequence, a sequence must be long and varied enough to offer a valuable correlation. Moreover, correlation may indicate a causality link if the correlation index is extremely high.

The probability of finding an identical copy of a given DNA fingerprint is below 10^{-10}. Since the human population has not reached 10^{10} yet, fingerprinting provides a valid legal proof of identification. There is a large difference in the probability of occurrence of a given microsatellite with that of a transversion.

Few chemicals are legally recognized carcinogens. For instance, asbestos, a mineral, causes a unique and almost exclusive type of tumor called *mesothelioma*. Another compound, radioactive iodine, ingested by Ukrainian children in the aftermath of the Chernobyl nuclear accident is instrumental in breaking a specific chromosome in thyroid cancer cells. That type of causal relationship between mutations induced by radioactive iodine and a specific tumor is rather infrequent in practice. The probability for carcinogens to leave a ''mutational signature'' on DNA is so low that this concept has never been accepted as evidence in court.

9
Humans Use Mutagenesis to Produce their Immunity Repertoire

Mutations in DNA sequences in the immunoglobulin locus are involved in *class switch recombination* (CSR). These mutations are base substitutions, deletions, or duplications. Such mutations are primarily dependent upon the *induced activation of cytosine deaminase* or AID. One finds them during *V gene somatic hypermutation*. A correlation between a pattern of mutations and a mutational complex might generate them. This is due to the observation of the V gene mutation pattern of XP-V patients afflicted with the cancer-prone *Xeroderma pigmentosum variant syndrome*. The patients are deficient in DNA polymerase η (polη), suggesting that this enzyme is responsible for a large part of the mutations occurring at A–T bases. After analysis of switched memory B cells from two XP-V

patients, it has been deduced that polymerase polη is also an A–T mutator during CSR, in both the switch region of tandem repeats as well as upstream of it. This suggests that the same error-prone translesional polymerase is involved, together with AID, in *CSR*.

Acknowledgments

It is a pleasure to acknowledge Li and Graur for their figure models. I also thank Pr. Joann Sweasy (Yale University) and Dr. Evelyne Sage (Institut Curie) for their insightful comments, and also thank Mrs. Melanie Pierre for her kind and indefatigable help.

Keywords

Deletion Bias
The study of small insertions and deletions (indels) in most eukaryotes shows an excess of deletions over insertions, forecasting DNA loss.

Effective Population Size (*Ne*)
A theoretical number of individuals that would explain the amount of genetic variation observed within a species in the absence of selection. *Ne* is somewhat related to, but always smaller than, the actual number of individuals. *Ne* is positively associated with the effectiveness of selection and varies among species as well as across genomes.

The amount of haploid nuclear DNA (or C-value) among eukaryotes varies more than 4 orders of magnitude, with brewer's yeast *Saccharomyces cerevisiae* (1.2×10^7 bp) or the parasitic microsporidium *Encephalitozoon intestinalis* (3×10^6 bp) as prototypical examples of the smallest genomes and several amoebae mentioned as the eukaryotes with largest genomes with $>6 \times 10^{11}$ bp (e.g. *Amoeba dubia* and *Chaos chaos*). Differences in the amount of noncoding DNA are also observed within a given taxonomic group, with algae varying more than 5000-fold, more than 1000-fold among flowering plants or invertebrates, more than 300-fold among vertebrates, and 100-fold among amphibians and insects. An apparent ''paradox'' arises when the size of the nuclear genome is compared to organismal complexity (morphological or developmental) if we assume that the amount of genetic material (genome size) should somehow correspond to the amount of genetic information. The so-called C-value paradox or enigma was coined to describe this lack of correspondence. Later findings revealed that coding sequences account for only a small proportion of the genomic DNA in most eukaryotes. This observation does not solve the C-value paradox, but shifts the debate from the number of genes responsible for a given degree of complexity (the G-value paradox) to the amount of noncoding DNA and the causes for its tremendous variation. In fact, recent studies based on fully sequenced genomes and expression data in model eukaryotes, including humans, have shown that complex gene regulation and the number of different transcripts – with a high fraction of genes having multiple transcripts – and not the number of genes, would better represent biological ''complexity,'' hence explaining the G-value paradox.

1 The C-value Paradox

Many cause/consequence relationships have been proposed on the basis of phenotypic correlations. The variation in noncoding genome size among eukaryotes has been associated with biological factors, both cellular and organismal: cell and nucleus size, cell division rate, metabolic rate, developmental rate, developmental complexity, and overall gene expression.

Indeed, eukaryotes with large genomes tend to have larger nucleus and cells, and species with high developmental rate to developmental complexity ratio tend to have reduced genomes; other associations are only observed in particular lineages.

However, an aspect not always considered is that many biological factors are associated with species or population parameters such as generation time, population size, and effective population size (*Ne*). This indirect association between cellular or developmental factors and *Ne* is pertinent in the analysis of any genomic characteristic (or any biological feature for that matter) because *Ne* is a main parameter influencing natural selection. Population genetic theory predicts and evolutionary analyses confirm that *Ne* is positively associated with the effectiveness of selection. (Increased effectiveness of selection will favor the fixation of advantageous mutations and the removal of deleterious mutations.) As a consequence, it is not direct to distinguish between cause, effect, and indirect or coincidental association; many proposed causal associations illustrate this difficulty. For instance, a causal association between fast developmental rate (and short generation time) and small genomes can be proposed. However, many species with short generation time also have large population sizes and *Ne*, and therefore the observed small genome is likely the result of more efficient selective constraints favoring small genomes while the negative relationship between developmental rate and genome size would be secondary.

Moreover, several cases of closely related species – with equivalent cellular and developmental parameters – exemplify that the size of noncoding DNA can change very rapidly in evolutionary terms independent of biological factors. For instance, closely related Drosophila species show severalfold differences in noncoding DNA and there is significant variation even at intraspecific level. Another piece of information comes from genomic analyses that have shown that several features of noncoding DNA such as the amount of intergenic DNA (or gene density), and intron presence and size also show a heterogeneous distribution across genomes. Thus, an integral explanation to the presence and size of noncoding DNA should be able to explain differences between distant groups or taxa, differences between closely related species with equivalent cellular/developmental features, as well as differences across a given genome.

2 Noncoding Genome Size: Passive versus Selective Trait

One possible explanation to the size of noncoding DNA and genome size in eukaryotes is that the amount of noncoding DNA is the passive result of mutational tendencies only; the manifestation of a mutation-drift equilibrium between insertions and deletions. Under this mutational-only scenario, variation in genome size is explained by differences in the patterns of insertion and deletion of ''selfish'' DNA or due to variation in the intrinsic rates of DNA loss through small insertions and deletions (indels). Special attention has been paid recently to the latter process, with several eukaryotes showing an excess of small deletions over insertions (the so-called deletion bias; DB). In particular, it has been proposed that differences in the rate of DNA loss caused by small indels are a major factor influencing genome size.

Under a selective scenario, genome size represents the equilibrium of mutational

tendencies to either increase or decrease the amount of DNA counterbalanced by selective tendencies: a mutational selection–drift equilibrium. Mutational tendencies can certainly vary among species, with differences in the amount of repetitive DNA and its tendency to expand in the genome (mostly associated with transposable elements; TE), as well as variation in DB. It follows, however, that a mutational-only hypothesis – which assumes that the presence of noncoding DNA has no fitness costs – would predict either the collapse of noncoding DNA or the unlimited expansion of noncoding DNA. A more likely proposal assumes that both mutational tendencies (DNA expansion by TE amplification and DNA loss by DB) are balanced as a result of selective constraints.

The selective causes acting on genome size can be varied and be particular to groups or taxa according to specific cellular or developmental requirements (e.g. fast cell division), targeting replication costs, or biological effects of bulk DNA. As indicated earlier, the effectiveness of selection acting on noncoding DNA would also depend on parameters such as *Ne* and recombination (see the following) and so the outcome of the equilibrium would be species specific. Moreover, both *Ne* and recombination vary across genomes. Thus, a mutation selection–drift equilibrium is expected to be highly variable among taxa, between closely related species, and also vary across a given genome.

3
Deletion Bias (DB) Based on Small Indels

3.1
DB in Drosophila

The struggle to determine the mutational DB on the basis of small indels is best exemplified in Drosophila, in which three different approaches give three different results. The first significant attempt to investigate DB in Drosophila, studied nonallelic copies of non long–terminal repeat retrotransposable elements, so-called ''dead-on-arrival'' (DOA) elements. The study of *Helena* DOA elements gives a DB of 8.7, suggesting a very high rate of DNA loss. The second approach investigated defective TEs, generating a DB of 3.6. The third approach is the study of indels at polymorphic level in DNA sequences likely free of selective constraints (intergenic regions and introns), with a DB that ranges between 1.4 and 1.9, evidencing a significant but moderate rate of DNA loss.

3.2
What is the True DB in Drosophila?

As indicated by B. Charlesworth, the study of nonallelic DOA elements (that are either fixed or segregate at high frequencies within a species) could bias the estimates of DB if selection favors deletions in recently inserted elements, hence causing an overestimation of DB. The rational for arguing selection against inserted repetitive elements (favoring deletions and shorter versions of the elements) is based on the notion that shorter elements would reduce the probability of ectopic recombination and its deleterious effects. On the other hand, population genetic theory predicts that polymorphic studies will estimate mutational parameters that can only be closer to the true values compared to analyses that use mutations that are either fixed or segregate at high frequencies within a species. If indels are neutral, all approaches should give equivalent results, but if indels are under weak/moderate

selection, the study of indels at polymorphic level is least influenced by selection. Strong selective constraints on the sequences used to investigate polymorphic indels, however, could also reduce the number of deletions observed at polymorphic level, hence causing underestimates in DB.

Several observations suggest that the estimates of DB based on different polymorphic studies is close to the true DB. First, an *ad hoc* theoretical model presuming that long deletions in introns are under strong selection would forecast a lower DB, but even in this case it cannot explain the observed data. Second, the study of polymorphic indels in intergenic regions also produces a very low DB (1.7) and, therefore, the argument that the observed DB is biased because of selection is not likely to be correct. And third, a recent study on the frequency of several families of TEs in populations has generated a key result to understand the observed discrepancy in DB based on long repetitive elements. This study shows that there is a negative correlation between the length of TEs within a family and the frequency in the population, in agreement with the ectopic recombination model that claims that deletions would be selectively favored in long repetitive elements. The consequence of this observation is that estimates of DB based on long repetitive elements will be biased, showing an excess of deletions than those expected by mutational tendencies only.

3.3 DB in Other Eukaryotes

Measures of DB have been obtained in other eukaryotes also on the basis of different approaches. One of the first studies to detect an excess of small deletions over insertions was applied to mammals by analyzing processed pseudogenes. Large-scale analyses of pseudogenes in humans and murids show an average DB of 2.74. The study of pseudogenes in the insect *Podisma pedestris* and in *Caenorhabditis elegans* shows DB of 2.7 and 3.8, respectively. The study of DOA *Lau1* elements in the Hawaiian crickets of the genus *Laupala* and *Maui* elements in two pufferfish species suggests a DB of 2.7 and 1.3–2.0, respectively.

3.4 Overall Rate of DNA Loss due to Small Indels and Genome Size

The rate of DNA loss depends on DB as well as the size of indels, and in most species deletions are longer than insertions. In order of increasing genome size, the overall rate of DNA loss observed in the different eukaryotes is the following: 1.8 in *Drosophila melanogaster* (based on polymorphic indels in intergenic regions and introns), 9 to 15 in Pufferfish, 3.8 in Laupala, 2.6 in rat/mouse, 1.7 in humans, and 3.6 in Podisma. Conversely, *C. elegans* shows a net gain of DNA based on small indels. As T.R. Gregory concluded recently, the use of updated estimates of DNA loss for mammals and Drosophila raise considerable doubts about the strength of any correlation between DNA loss rate by small indel bias and genome size. Therefore, although the mutational rate of DNA loss caused by small indels can vary evolutionarily, and might itself be the result of selection, it cannot explain the observed differences in noncoding DNA content and genome size between species. Moreover, this mutational explanation cannot account also for the observed differences across genomes.

4 Transposable Elements (TE) and DNA Gain

TE elements are widespread in eukaryotic genomes and comprise in many cases a substantial portion of euchromatic genome size, including humans where TEs explain 45% of intergenic and intronic sequences. The recent invasion/amplification of particular TE families causes rapid increases in genome size, temporarily altering any specific equilibrium among selective and long-term mutational tendencies. Two examples of such effect are maize, in which genome size has recently doubled due to TE invasion, and Drosophila, with substantial differences in TE presence between closely related species, as well as among populations of the same species. The opposite trend is also detected, with species that have recently lost repetitive DNA showing a sudden reduction in genome size albeit having similar mutational tendencies associated with small indels. For instance, tetraodontid (smooth) and diodontid (spiny) pufferfish have similar DB but smooth pufferfish shows a twofold reduction in genome size because of a recent reduction in repetitive elements. This latter case also illustrates that any study of mutational tendencies toward DNA gain or loss should include small indels (i.e. DB), as well as the rate of large insertions and TE amplification.

It is possible to argue that a generic mutational tendency of TE to replicate and increase genome size might have favored a mutational mechanism associated with DNA repair of small indels with a tendency toward DNA loss, as observed in most eukaryotes. In this regard, small differences in DB among taxa would reflect long-term tendencies associated with TE amplification in the genome. The additional influence of selective forces that can be species specific and/or vary across genomes would generate the final outcome.

5 Variation across and among Genomes: The Influence of Recombination

Many genomic analyses have revealed heterogeneity of noncoding DNA presence across eukaryotic genomes. In Drosophila, the amount of intergenic DNA is higher in genomic regions with low recombination (and crossing-over) rates. Introns are also longer and more frequent in genes located in regions with severely reduced rates of crossing-over. An equivalent trend is observed in humans, with longer intergenic sequences, and introns in isochores are associated with reduced rates of crossing-over. *S. cerevisiae* also shows an influence of recombination on the presence of noncoding DNA. A single exception to this tendency is observed in *C. elegans,* in which an atypical pattern of crossing-over along chromosomes has been reported.

Interestingly, a negative relationship between recombination rates and the amount of noncoding DNA is observed among species. The study of nine distant eukaryotes with well-characterized genetic and physical maps (Fig. 1) reveals a significant negative relationship between recombination rate and a measure of the amount of noncoding DNA once the number of genes is taken into account. (Albeit the study is based on a small number of species, the observed relationship is not caused by any single species.) This observation suggests that similar, or at least overlapping, forces are shaping the size of noncoding DNA among species and

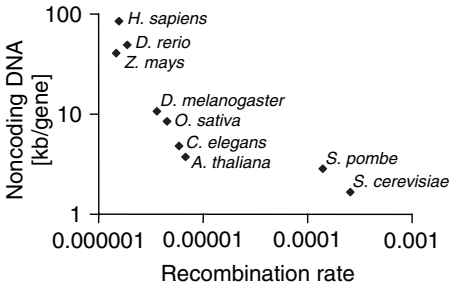

Fig. 1 Relationship between recombination rate and gene density among evolutionary distant model eukaryotes. The nine eukaryotes with well-characterized genetic and physical maps are: *Homo sapiens*, *Danio rerio* (zebra fish), *Zea mays* (maize), *Oryza sativa* (rice), *D. melanogaster*, *C. elegans*, *Arabidopsis thaliana*, *S. cerevisiae*, and *Schizosaccharomyces pombe* (fission yeast). Recombination rate indicates the average percentage of meiotic recombination (cM) between adjacent base pairs (total genetic map/total physical map), taking also into account the number of chromosomes to appraise the recombination caused by the random segregation of chromosomes. Although *A. thaliana* is a predominantly selfing plant, this feature has only recently been acquired, with all closely related species being outcrossing and, therefore, the recombination rate used for *A. thaliana* reflects the recent ancestral outcrossing condition. Nonparametric Spearman's rank correlation $R = -0.95$ ($p = 0.00009$). The least significant relationship after removing any one species is $R = -0.929$ ($p = 0.0009$). The removal of both distantly related yeasts (*S. cerevisiae* and *S. pombe*) from the analysis does not influence the outcome either ($R = -0.893$, $p = 0.007$).

across genomes. These equivalent findings across and among genomes could be explained if the mechanism of mismatch repair associated with recombination instigates DNA loss. Although this possibility needs to be investigated thoroughly in different species, in *D. melanogaster* there are similar patterns of indels in regions with normal and reduced rates of crossing-over.

An alternative explanation, invoking natural selection, emerges when we consider the influence that recombination has on the effectiveness of selection. Indeed, theoretical and experimental investigations predict that recombination will have an impact on the power or effectiveness of selection. In particular, most models of selection forecast that recombination will raise the effectiveness of selection. The total length of genetic map in a species as well as the number of chromosomes will play a role in the total meiotic recombination rate. Recombination rates and *Ne* (mentioned earlier) are two parameters that have been usually limited to population genetics studies but they should be included in any general explanation to genome architecture, the amount of noncoding DNA and genome size due to their influence to the effectiveness of selection. Moreover, both recombination and *Ne* are influenced by species-specific factors as well as vary across genomes.

6 Noncoding DNA is not Free of Genetic Information or Evolutionary Effect

Noncoding DNA in eukaryotes has been often labeled as "junk" DNA, useless (with no genetic information) as well as with no evolutionary effect (neutral to selection). In fact, however, noncoding DNA can be evolutionarily relevant by containing genetic information as well by its only presence. The number of known noncoding genes and especially noncoding RNA genes (ncRNA) has recently increased rapidly. Many of these ncRNA function directly as RNA while others play an essential role in gene regulation, with antisense RNAs being an important class of these genes. Moreover, noncoding DNA,

intergenic or intronic, harbors most of the information on gene regulation.

On the other hand, the presence of DNA with no genetic information between genes or between exons should not be assumed to be devoid of evolutionary effect. For instance, the presence of introns and their length can have a direct fitness effect on transcription costs and be a trait under selection. However, the presence of DNA sequences with no direct fitness effects can also be a selective trait. Note that the significant parameter associated with recombination is the total recombination between genes or exons (i.e. clusters of sites under selection) and this is influenced by the rate per physical unit as well as by the physical distance. Therefore, under realistic conditions for most eukaryotes, an organism might increase the effectiveness of selection by increasing the amount of noncoding DNA, intergenic or intronic. Under this scenario, the presence of ''junk'' DNA can be viewed as a modifier of recombination with a definite evolutionary long-term effect and can itself be a selective trait. The long-term fitness effects of increasing the physical distance between clusters of sites under selection (genes, exons, or regulatory regions) and recombination, is expected to differ among species (according to the overall recombination rate) and across genomes (according to variation in recombination rates along chromosomes).

7 Summary

The study of noncoding DNA is no longer restricted to phenotypic correlations and all recent observations support the notion that noncoding genome size in eukaryotes is the result of a highly dynamic balance between mutational and selective forces. Population parameters that influence levels and patterns of polymorphisms also influence the effectiveness of selection and have the potential to influence genomic features. Therefore, the evolution of noncoding DNA (intergenic and intron presence, and size) ought to be investigated from a population genetics perspective (i.e. the so-called *population genomics* approach). The presence of regulatory sequences and noncoding genes (e.g. ncRNA genes) would add genetic information required for organismal ''complexity,'' but it can explain only a fraction of noncoding DNA.

Mutational tendencies are strongly influenced by TE invasion and amplification, which can be species specific and cause sudden changes in genome size. This ''one-way ticket to genome obesity'' is somewhat counteracted by a moderate tendency toward DNA loss due to small indels observed in most eukaryotes. The widespread presence of TEs in eukaryotes might have caused a selective pressure on mechanisms of DNA repair favoring DNA loss. The study of small indels only cannot produce an accurate picture of mutational tendencies. On the other hand, selective forces on the presence of noncoding DNA can vary in different species and/or taxa and be associated with replication costs, nuclear architecture, or other biological effects of bulk DNA. Importantly, the actual impact of these selective tendencies is determined by recombination rates and *Ne* parameters that can vary across genomes, as well as among species and should be included in any general explanation to genome evolution. Future studies on variation of recombination rates, indel evolution, and *Ne* in many eukaryotes will give us a broader and more

precise picture on the selective and mutational forces influencing the evolution of noncoding DNA.

Keywords

Adherens Junctions
Cell–cell junction, mediated by the cadherins, which are transmembrane proteins that form contacts with each other extracellularly and anchor to the actin cytoskeleton via catenins, intracellularly.

Anchorage Dependence
The dependence for cells to attach to an extracellular matrix, mediated by integrins, before progression from G1 to S phase can occur.

Cdk Inhibitor (Cki)
Proteins of two different classes that act to inhibit Cdks; the CIP(KIP)-family proteins ($p21^{CIP1}$, $p27^{KIP1}$ and $p57^{KIP2}$) bind to and inhibit Cyclin/Cdk activity, while the INK4 family ($p16^{INK4A}$, $p15^{INK4B}$, $p18^{INK4C}$ and $p19^{INK4D}$) bind to Cdk4(6) and prevent Cyclin binding to the Cdk.

Cell Growth
The increase in cell mass due to increased rates of mRNA and protein synthesis that is distinct from cell proliferation, which is an increase in cell numbers due to passage through the cell cycle.

Cell Polarity
The structure or shape of a cell, which is determined by the specific location of membrane-localized protein complexes along the apical–basal axis.

Centrosome (Microtubule-organizing Center, MTOC)
An organelle that is duplicated at the onset of S phase, and functions in mitosis to nucleate microtubules to form the mitotic spindle.

Checkpoint
A surveillance mechanism preventing cell cycle progression until a particular event is completed. G1-DNA-damage checkpoint arrests cells in G1 until DNA damage can be repaired. DNA-replication checkpoint, blocks cell cycle progression into mitosis when DNA replication is inhibited.

Contact Inhibition
The arrest of the cell cycle in G1 phase that occurs when cell density increases to confluence in culture, mediated by cell–cell contact via cadherins at the adherens junction.

Cop9 Signalosome (CSN)
A complex that is required to cleave Nedd8 (a ubiquitin-like protein) from Cullin proteins in the SCF and that is important for SCF activity.

Cyclin
The regulatory subunit required for the activity of cyclin-dependent kinases, many of which are unstable proteins, regulated by ubiquitin-mediated proteolysis.

Cyclin-dependent Protein Kinase (Cdk)
A family of serine–threonine protein kinases, which require the binding of a cyclin subunit for activity. Cdk1, 2, 3, 4, and 6 are required for progression through specific cell cycle phases.

Extracellular Matrix
An organized array of extracellular proteins, such as laminin and fibronectin that acts as anchors and receptors for the basally localized transmembrane proteins, integrins.

Mitogen
An extracellular growth factor that stimulates cell growth and proliferation.

Prereplication Complex (Pre-RC)
A protein complex, composed of ORC1-6, Cdc6, Cdt1, and MCM2–7, that binds to origins of DNA replication in G1 phase, and is required to set the origins for the initiation of DNA replication.

Restriction Point
A point late in G1, where a cell becomes committed to enter and complete an entire cell cycle independent of the presence of growth factors. Defined by the inactivation of the retinoblastoma tumor suppressor protein by Cyclin/Cdk phosphorylation.

SCF
A complex containing, Skp1, Cullin, and an F-box protein, and Rbx1 (or Roc1, Hrt1, a ring-finger protein) that acts as an E3 ubiquitin ligase. The F-box protein (such as Skp2, Ago/Fbw7, or Slimb) confers substrate specificity.

Septate Junctions
Drosophila cell–cell junctions, located basal to the adherens junctions, where Scribble and Dlg are located.

Tissue Architecture
The three-dimensional arrangement of individual cells to each other, which creates the organized structure of a tissue in a whole organism. It is mediated by the polarity of individual cells and the linkage of adjacent cells via intercellular junctions.

Tumor Suppressor
A protein that acts to prevent cell proliferation and tumorigenesis, and is inactivated in cancers.

Ubiquitin Ligase (E3)
A protein complex that transfers ubiquitin (a 76-residue protein) from an E2 ubiquitin-conjugating enzyme to the substrate, thereby tagging it for ubiquitin-mediated degradation.

It is critical to strictly regulate cell proliferation for the faithful duplication of DNA and the transmission of chromosomes to the next generation. This fundamental cellular process is known as the *cell cycle*. The cell cycle has been extensively studied since the 1970s, and many seminal studies have elucidated cell cycle regulatory mechanisms and how these controls fail in proliferative disorders, such as cancer. This review focuses on the underlying mechanisms that regulate the progression of cells into the DNA-replication phase (the G1-S phase transition), since it is at this stage in mammalian cells where cell proliferation is predominantly regulated. To enter into S phase, cells must pass a stage known as the *restriction point* where the cell monitors the relative level of positive versus negative extracellular signals, before it commits to progress into and completes an entire cell cycle. Key protein kinases, the cyclin/Cdks, are critical in progression past the restriction point. It is at this stage that cyclin/Cdks phosphorylate and inactivate the tumor suppressor protein, retinoblastoma (Rb), which acts to block the activity of the E2F S-phase gene transcription factor. The accumulation and activity of cyclin/Cdks is determined by the level of cyclin transcription, translation, and proteolysis, and in turn affect the production of Cdk inhibitors that block Cdk activity. Extracellular signals, via growth factors and from contacts between cells or the extracellular matrix, influence the accumulation and activity of cyclin/Cdks and are critical in determining whether

the cell will progress into S phase. Environmental assaults also impact on the G1-S phase progression, and lead to the upregulation of the p53 tumor suppressor protein, which by upregulation of Cdk inhibitors results in G1-S phase arrest until DNA damage or DNA-replication defects can be repaired. In S phase, a cell needs to duplicate the centrosome (an organelle required for the separation of chromosomes in mitosis) and to initiate DNA replication, which depends upon cyclin/Cdk phosphorylation of specific targets. The establishment of DNA-replication origins and the process of DNA-replication initiation is a highly regulated process, to ensure that the DNA is completely replicated once, and only once, per cell cycle. However, in particular, developmental situations in Drosophila and mammals, there are different modes of DNA replication, known as the *endoreplication cycles*, which result in amplification of the genome or parts of the genome without mitosis. The switch from the canonical cell cycle to the endoreplication cycles is also tightly regulated. Thus, the G1-S phase transition is a strictly regulated process, whose control within a whole organism is essential for limiting cell proliferation, and which when dysregulated can lead to cancer.

1
Overview of the Cell Cycle: An Historical Perspective

1.1
Stages of the Cell Cycle

The cell cycle is the process by which cells reproduce. For a eukaryotic cell, this requires the duplication of DNA and the faithful segregation of chromosomes into two daughter cells. When researchers first examined dividing cells under the microscope, they noted that most of the time little activity could be detected, but within a short time period the cell exhibited a dramatic rearrangement of cellular architecture where chromosomes were segregated into daughter cells. The cyclic stage of chromosome segregation was termed *mitosis*, and the rest of the cell cycle was termed *interphase*. It is now known, that within interphase, the continuous process of cell growth (the accumulation of cell mass) occurs, and at a defined stage, DNA replication occurs. To monitor DNA replication, cultures of eukaryotic cells could be synchronized at specific stages of the cell cycle (by nutrient or serum starvation or by using drugs to block DNA replication or mitosis) and cells labeled with the nucleotide analogs, H^3-thymidine or bromodeoxyuridine. These studies showed that DNA replication occurred at a precise stage in the cell cycle, termed *S phase*.

Thus, the eukaryotic cell cycle can be divided into four major phases; G1, S phase, G2, and mitosis (M phase). During the replication period (S phase), the genetic information is duplicated and then distributed into the two daughter cells during mitosis (M phase). These two phases are separated by so-called *Gap phases*, the G1 phase and the G2 phase. In most eukaryotic cell cycles, the G1 phase is where the most critical regulatory decisions are made. It is at this stage where, depending upon extracellular signals, the cell makes the decision to

commit to another complete cell division or to enter G0 (quiescence). The cell also needs to grow, to accumulate cell mass (including the synthesis of new RNA, proteins, ribosomes, organelles, and membranes) to acquire a critical cell size before committing to enter the cell cycle. In most mammalian cultured cells, the cycle time is 24 h, consisting of G1 (12 h), S phase (6 h), G2 (6 h), and mitosis (0.5 h). A notable exception are cultured embryonic stem cells which have a modified cell cycle circuitry that enables a 6 h cell cycle. Similarly, the cell cycle time in other organisms can be considerably shorter. For example, in budding yeast (*Saccharomyces cerevisiae*) or fission yeast (*Schizosaccharomyces pombe*) the cell cycle time is ~2 h, while in the developing embryos of the vinegar fly *Drosophila melanogaster*, it can be as little as 8 min. The rapid cell cycles, in yeast are due to their smaller genome size and the presence of abundant nutrient supplies, while in the Drosophila embryo, maternal contribution of all critical proteins allows DNA replication and cell division to occur rapidly, without the need for cell growth.

1.2 Existence of Cell Cycle Controls

Cell fusion studies carried out in the 1970s by Rao and Johnson, first revealed that progression through the cell cycle is a regulated process. These studies utilized the fusion of cells that were at different points in the cell cycle to demonstrate that there is an S phase–inducing activity present in S-phase cells, and an M phase–inducing activity in mitotic cells. In addition, these studies showed that there are *checkpoint controls* (surveillance mechanisms that block cell cycle transitions until a particular event is complete) that prevent rereplication of DNA and entry into mitosis prior to the completion of DNA replication.

Subsequent studies revealed additional checkpoint controls in cell cycle regulation. In the budding yeast, there is a checkpoint that monitors cell size (to ensure adequate growth), the presence of appropriate levels of nutrients and the absence of extracellular mating factors (a or α-pheromones), before allowing the cell to enter the cell cycle. This critical point, where a cell becomes committed to the cell cycle, is called *start* in yeast, while in more complex eukaryotes this checkpoint is called the *restriction point* (defined as the point, that once passed, a cell becomes committed to enter and complete a cell cycle without the need for growth factors). In multicellular eukaryotes, nutrient levels are less important, while the presence of positive or negative extracellular signals, such as growth factors and signals from neighboring cells or the extracellular matrix (ECM), determines whether a cell becomes committed to enter into the cell cycle, or exits the cell cycle into a quiescent (G0) state or differentiates.

1.3 Approaches to Analyze the Cell Cycle

The first molecular approaches to the analysis of the cell cycle came from two different camps; (1) the biochemical approach using mammalian cultured cells and the oocytes of marine organisms, and (2) the genetic approach using the budding yeast (*S. cerevisiae*) or fission yeast (*S. pombe*). From the biochemical approach, two seminal discoveries were made. First, the first members of a family of important regulatory proteins, the

cyclins, were purified from the eggs of marine organisms. These cyclins were so called because they varied dramatically in abundance during the cell cycle, and also because of their cyclic synthesis and destruction. Second, the factor important in driving the cell cycle (mitosis promoting factor, MPF) was identified and purified, and its molecular nature determined by protein sequencing. The genetic approach was based on the isolation of conditional lethal mutants (temperature-sensitive mutants that were viable at 20 °C but lethal at 37 °C) that affected the cell cycle, and their subsequent phenotypic characterization enabled the identification of important cell cycle functions. Genetic analysis revealed hierarchical relationships between genes in cell cycle control (see Fig. 1). Moreover, complementation cloning and DNA sequencing enabled the identification of the cell cycle gene at a molecular level.

In the late 1980s, studies from the genetic and biochemical perspectives converged to reveal that the proteins identified to be key drivers of cell cycle progression in marine organisms and in mammalian cultured cells, were the same as those identified by genetic studies in yeast. Thereby, the cell cycle engine components were revealed to be a family of serine–threonine protein kinases, the cyclin-dependent protein kinases (Cdks) and their regulatory subunits, cyclins. The cyclin-Cdk complex, in its various different flavors, was subsequently shown to be conserved in all eukaryotes and to drive progression from G1 to S phase and from G2 to M phase.

This review will focus on the G1-S phase transition and the initiation of DNA replication. In this review, we will primarily focus on analyses of mammalian cultured cells and *in vivo* studies using multicellular animal model systems, the mouse and the fly, Drosophila. We will describe the key events of G1-S phase, the regulators of the G1-S phase progression, modes of regulation of the key regulators, the signaling pathways that regulate G1-S phase progression, the control of

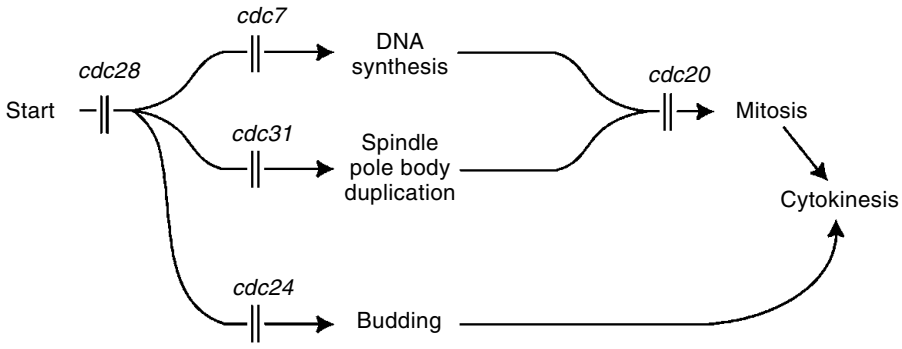

Fig. 1 Genetic analysis of yeast cell cycle mutants. Genetic analysis of budding yeast (*S. cerevisiae*) cell cycle mutants defined a cell cycle pathway. Mutants in specific genes blocked particular aspects of the cell cycle, thus revealing the cell cycle function of many genes. Mutants in *cdc7* blocked DNA synthesis, in *cdc31* blocked duplication of the spindle pole body (the yeast equivalent of the centrosome), in *cdc24* blocked cell budding (an event specific to the biology of budding yeast), and in *cdc20* blocked mitosis. Importantly, mutants in *cdc28* (*cdc2*, *cdk*) blocked all events of the G1-S-phase transition. Thus, the function of Cdc28, a serine–threonine cyclin-dependent kinase (Cdk), defines the G1-S phase transition.

the initiation of DNA replication, and regulation of alternative modes of DNA replication.

2 The Molecular Basis of G1-S Phase Regulation

2.1 Events of the G1-S Phase Transition

In all eukaryotes, the G1-S phase transition is not only marked by the initiation of DNA replication but by another key event also, that of centrosome duplication. The centrosome, or the microtubule-organizing center, is an organelle required for the nucleation of microtubules in mitosis, and undergoes duplication at the G1-S phase transition. In addition, in budding yeast, the initiation of bud formation is another key event that characterizes passage into S phase. Genetic studies in yeast, have revealed mutations that block either DNA replication, centrosome duplication or budding, but mutation of only one gene, *cdc28*, encoding the yeast Cdk, blocks all three of these events (see Fig. 1). Thus, in budding yeast, the Cdk, Cdc28, is the key regulator of all the events of the G1-S phase transition, and therefore is said to be the regulator of *start*. In higher eukaryotes, while more complexity exists (see the following), Cdks are also critical for passage through the *restriction point* and entry into S phase.

In G1, the cell responds to the presence of nutrients in the case of yeast, and to the presence of positive growth factors in higher eukaryotes, by activation of signaling pathways that result in the accumulation of G1-phase cyclins. In addition, at the G1-S phase transition, transcriptional programs are initiated, which lead to the coordinated expression of genes required for DNA replication, the so-called *S-phase genes*. The regulators of the events of the G1-S phase transition and the molecular mechanisms controlling them will now be discussed.

2.2 Key Regulators of the G1-S Phase Transition

2.2.1 Cyclins and Cyclin-dependent Kinases (Cdks)

As discussed earlier, the key molecules involved in progression through the cell cycle are the cyclin-dependent protein kinases (Cdks) and their regulatory component, cyclins. Cyclins are characterized by a sequence motif of about 100 amino acids called the *cyclin box*, which is sufficient for association with Cdk proteins. The structural changes brought about by the binding of a cyclin to a Cdk have been investigated by X-ray crystallography using human Cyclin A and Cdk2. Monomeric Cdk remains inactive due to an α-helical region (αL12) that constrains the ATP-binding site and a ''T-loop'' domain that blocks the catalytic cleft. The binding of cyclin to the Cdk shifts the inhibitory T-loop domain and ''melts'' the αL12 helical region, allowing substrates to bind to and be phosphorylated by the Cdk.

Specific activation of Cdk activity during the cell cycle is achieved by the cyclic synthesis and destruction of cyclins. Different cyclins peak in abundance at different points in the cell cycle, which is due to both transcriptional regulation of *cyclin* gene expression and to cell cycle regulated ubiquitin-mediated proteolysis of the cyclin protein.

In yeast, there is only one Cdk (Cdc28 in *S. cerevisiae* or Cdc2 in *S. pombe*), which

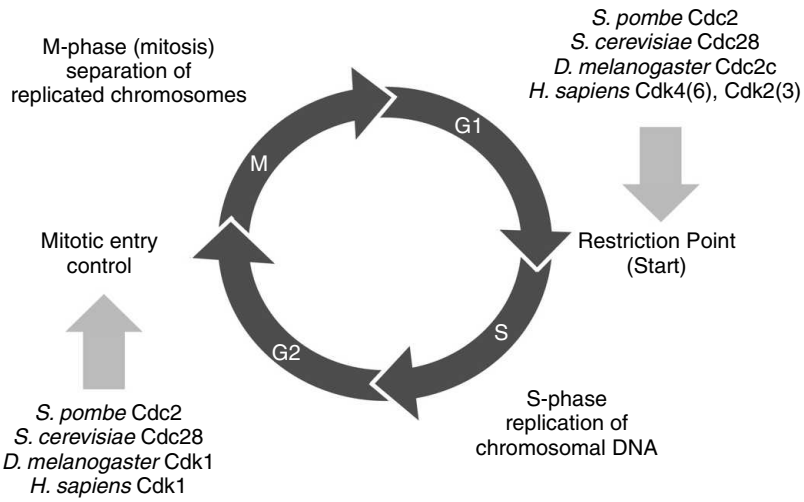

Fig. 2 Role of Cdks in cell cycle progression. The G1-S phase transition is driven by Cdc28 in *S. cerevisiae*, Cdc2 in *S. pombe*, Cdc2c in Drosophila, and by Cdk4(6) and Cdk2(3) in mammalian cells, while the G2-M phase transition is driven by Cdc28 in *S. cerevisiae*, Cdc2 in *S. pombe*, Cdk1 in Drosophila, and by Cdc2 (also termed *Cdk1*) in mammalian cells. The restriction point (or start in yeast) is a point late in G1 where cells become committed to enter and complete an entire cell cycle.

by association with different cyclins, regulate progression through the cell cycle (see Fig. 2). While in more complex eukaryotes, there are multiple Cdk family members that in association with different cyclins, have specific roles in G1-S or G2-M transitions (Fig. 2). In mammalian cells, Cdk1 is the primary protein kinase involved in the G2-M phase transition, while Cdk2 and Cdk3, and Cdk4 and Cdk6 play redundant roles in driving the G1-S transition.

In budding yeast, there are three groups of cyclins, Cln1-3, Clb5 and 6, and Clb1-4, which, in association with the Cdk, Cdc28, have specific roles during the cell cycle. Clb1-4 are important in the G2-M phase transition, while the Clns and Clb5(6) are essential for the G1-S phase transition. The Clns are important in initiation of bud formation while Clb5(6) are important for the initiation of DNA replication and for duplication of the centrosome (termed the *spindle pole body* in yeast). In addition, translational control of Cln3, in response to nutrient levels, has a role in coupling cell growth to cell division. In more complex eukaryotes, there are four major groups of cell cycle specific cyclins, Cyclin A1 and A2, B1-3, D1-3, and E1 and E2. These cyclins are more related to the yeast Clbs than the Clns; however, another cyclin, Cyclin C with a less defined role in cell cycle regulation (see the following), exhibits greater homology to yeast Clns. In mammalian cells, there are 11 Cdks that show strong homology to the yeast cell cycle Cdks; however, only Cdk1, 2, 3, 4, and 6 have specific roles in the G1-S and G2-M-phase transitions (Fig. 2). Mammalian cyclins associate with specific Cdks: Cyclin D associates with Cdk4 and Cdk6, Cyclin E with Cdk2 and Cdk3, Cyclin A with Cdk2 and Cdk1, and Cyclin B with Cdk1. Cdk1 functions at the G2-M phase transition,

while Cdk4(6) Cdk2(3) primarily function at G1-S and S phase. Cyclin A is unique in that it is able to interact with Cdk1 or Cdk2, and therefore has roles in G1-S and G2-M phase.

Studies in mammalian cultured cells have shown that Cdk2 has an essential role in the G1 to S-phase transition. In mammalian cells, Cyclins D, E, and A have different, essential roles in G1-S phase. Depletion of Cyclin D1, E, or A in cell culture by antibody injection or by using antisense results in G1 arrest, whereas overexpression of Cyclins D1, D2, E, or A promotes premature passage from G1 into S phase, showing that these cyclins are essential and rate limiting for G1-S progression. Furthermore, Cyclins D, E, and A have different roles during G1 and S phase, as revealed by the following results: (1) depletion of Cyclin D1 or E during G1 prevents entry into S phase, while depletion close to the initiation of DNA replication does not, while depletion of Cyclin A during S phase is able to inhibit DNA replication; (2) coexpression of Cyclin E and Cyclin D results in a greater acceleration of G1-S progression than expression of either cyclin alone. Thus, Cyclins D, E, and A act at different times during G1-S, and are likely to regulate different pathways during G1-S.

Specific aspects of the function of Cyclin D, E, and A will now be discussed, highlighting *in vivo* studies in Drosophila and the mouse.

2.2.1.1 **Cyclin A/Cdk2(3).** Cyclin A was first discovered by biochemical purification of a protein that showed dramatic fluctuation in the embryos of marine organisms, and was subsequently found to be conserved in all metazoans analyzed. In mammalian cells, *cyclin A* mRNA, protein, and associated kinase activity is present from late G1-M phase. As discussed earlier, Cyclin A can form complexes with Cdk1 and Cdk2 in mammalian cells, and can therefore have roles in the progression through the G1-S and G2-M phases.

While in mammalian cells there is evidence that Cyclin A/Cdk2 is required for entry into or progression through S phase, an S-phase role for Cyclin A in Drosophila is less clear. Drosophila Cyclin A interacts specifically with the mitotic Cdk, Cdk1, and not with the G1-S Cdk, Cdc2c, and *cyclin A* mutants arrest in G2 phase during embryogenesis (see Table 1). *Cyclin A* mutant embryos then enter ectopic endoreplicative Cyclin E-mediated S phases, indicating that Cyclin A is not normally required for S phase in Drosophila. There is, however, evidence that Cyclin A can function in the G1 to S phase transition, as ectopic expression of *cyclin A* can induce G1 cells to enter S phase.

In mammals, there are two Cyclin A homologs, Cyclin A1 and A2. In the mouse, Cyclin A1 is specifically expressed in the male germline and knockout of this gene results in male infertility (see Table 1). Cyclin A2 is more ubiquitously expressed in mouse development, and as such a mouse knockout of Cyclin A2 is early embryonic lethal (see Table 1), demonstrating the essential and nonredundant function of Cyclin A in cell proliferation *in vivo*. Conversely, overexpression of Cyclin A in mice leads to overproliferation and the development of cancer. The importance of appropriate control of Cyclin A *in vivo* is highlighted by the identification of Cyclin A as an oncogene in Hepatitis B-mediated hepatocellular carcinomas in humans.

2.2.1.2 **Cyclin E/Cdk2(3).** Human cyclin E was identified by its ability to rescue

Tab. 1 Phenotypes of knockouts/mutants of G1-S phase regulators in Drosophila and the mouse

	Drosophila (mutants)[a]	*Mouse (knockouts)*[b]		*Summary*
Cyclin D	Not yet characterized	$D1^{-/-}$	Viable with neurological defects, hypoplastic retina, and mammary glands	Dispensable for most embryonic cell cycles in the mouse.
		$D2^{-/-}$	Viable with fertility defects	
		$D3^{-/-}$	Viable with defects in T lymphocytes	
		$D1^{-/-}$ $D2^{-/-}$	Lethal neonatal with lack of cerebellar development	
		$D1^{-/-}$ $D3^{-/-}$	Lethal neonatal with neurological defects	
		$D2^{-/-}$ $D3^{-/-}$	Lethal neonatal with megaloblastic anemia	
		$D1^{-/-}$ $D2^{-/-}$ $D3^{-/-}$	Lethal E12.5-E16.5 with heart abnormalities and defects in hematopoietic stem cell expansion	
Cyclin E	Embryonic lethal. Essential for all cell cycles – maternal contribution until embryonic cycle 17	$E1^{-/-}$	Viable	Essential for G1-S in Drosophila, but dispensable for most cell cycles in mouse embryonic development.
		$E2^{-/-}$	Viable with reduced male fertility	
		$E1^{-/-}$ $E2^{-/-}$	Lethal E10.5-E11.5 due to endoreplication defects in placenta trophectoderm	
Cyclin A	Embryonic lethal – maternal contribution to cycle 16	$A1^{-/-}$	Viable with male infertility	Perform essential function(s) that cannot be compensated for by other Cyclins.
		$A2^{-/-}$	Lethal E5.5	
Cdk4/6	Viable with growth defects and reduced female fertility	$Cdk4^{-/-}$	Viable with proliferative defects in some endocrine cells	Dispensable for most cell cycles in Drosophila and the mouse. Mainly a regulator of cell growth in Drosophila.
		$Cdk6^{-/-}$	Viable with mild hematopoietic defects	
		$Cdk4^{-/-}$ $Cdk6^{-/-}$	Lethal late embryonic/neonatal with erythroid defects	
Cdk2	Larval lethal – maternal contribution during embryonic development	Viable with gonad atrophy and meiotic defects resulting in sterility		Consistent with requirement for G1-S in Drosophila and dispensability for most cell cycles in mouse development.

(*continued overleaf*)

Tab. 1 (*Continued*)

	Drosophila (mutants)[a]	*Mouse (knockouts)*[b]		*Summary*
P16-Ink4 family	Not present in Drosophila	$p15^{-/-}$	Viable with lymphoproliferative disorders and angiosarcomas	Not present in *Drosophila,* but play nonredundant roles in control of cell cycle exit and differentiation in multiple mammalian tissues.
		$p16^{-/-}$	Viable with thymic hyperplasia and increased tumor incidence	
		$p18^{-/-}$	Viable with increased body size and overgrowth of some organs, lymphoproliferative disorders, multiple cysts in kidney and mammary glands, pituitary tumors, and other malignancies	
		$p19^{-/-}$	Viable and fertile with males displaying testicular atrophy and progressive deafness	
		$p18^{-/-}$ $p19^{-/-}$	Viable with overlap of individual phenotypes and impaired spermatogenesis and infertility	
P21-Cip1 family	Embryonic lethal – maternal contribution of Dacapo until cycle 17; cells progress through another complete cell cycle.	$p21^{-/-}$	Viable and normal, cultured cells arrest inefficiently upon DNA damage	Essential for control of G1-S progression in Drosophila and important for control of cell cycle exit and differentiation in mammalian tissue.
		$p27^{-/-}$	Viable with increased body size and overgrowth of organs, female sterility, retinal dysplasia, and pituitary tumors with high penetrance	
		$p57^{-/-}$	Lethal neonatal with severe developmental defects including shortened limbs due to deregulated chondrocyte proliferation	
		$p21^{-/-}$ $p27^{-/-}$	Phenotype not characterized. Cultured cells defective in the formation of stable cyclin D–Cdk4 complexes	
		$p21^{-/-}$ $p57^{-/-}$	Lethal neonatal with skeletal muscle and lung alveoli defects	
		$p27^{-/-}$ $p57^{-/-}$	Lethal E12.5-E16.5 with hyperproliferation and differentiation defects in lens and trophoblast cells	

Rb	$Rbf1^{-/-}$	Larval lethal – maternal contribution during embryonic development	$Rb^{-/-}$	Lethal E13.5-E15.5 with defects in erythroid, neuronal, and lens development	pRb is important for cell cycle exit and differentiation of many tissues. P107 and p130 perform a redundant role in cell cycle exit and differentiation of chondrocytes and other tissues.
	$Rbf2^{-/-}$	Not yet characterized	$p107^{-/-}$	Viable	
			$p130^{-/-}$	Viable	
			$p107^{-/-}$ $p130^{-/-}$	Lethal neonatal – deregulated chondrocyte proliferation	
			$Rb^{-/-}$ $p107^{-/-}$	Lethal early embryonic	
			$Rb^{-/-}$ $p130^{-/-}$	Lethal early embryonic	
E2F	$E2F1^{-/-}$	Larval lethal	$E2f1^{-/-}$	Viable with thymic and testicular atrophy and increased tumor incidence	Dispensable for most cell cycles in Drosophila. Mouse activating E2F1/2/3 perform an essential function when repressive E2F4/5 are present. E2F6 is dispensable for cell cycle but has differentiation defects.
			$E2f2^{-/-}$	Viable with T cell defects; develop late onset autoimmune disease	
			$E2f3^{-/-}$	Lethal – neonatal, heart defects	
			$E2f1^{-/-}$ $E2f2^{-/-}$	Viable with defects in multiple hematopoietic lineages	
			$E2f1^{-/-}$ $E2f3^{-/-}$	Lethal – early embryonic	
			$E2f2^{-/-}$ $E2f3^{-/-}$	Lethal – early embryonic	
			$E2f1^{-/-}$ $E2f2^{-/-}$ $E2f3^{-/-}$	Lethal – early embryonic. Embryonic fibroblasts unable to enter S phase	
	$E2F2^{-/-}$	Weakly viable with reduced fertility	$E2f4^{-/-}$	Lethal neonatal, developmental defects including decreased size, intestinal, and hematopoietic defects	
			$E2f5^{-/-}$	Lethal neonatal, hydrocephaly	
			$E2f4^{-/-}$ $E2f5^{-/-}$	Lethal E16.5	
			$E2f6^{-/-}$	Viable with homeotic transformations of the axial skeleton	
	$E2F1^{-/-}/E2F2^{-/-}$	Pupal lethal			
DP	Larval/pupal lethal		$Dp1^{-/-}$	Lethal E9.5-E12.5 due to defects in extraembryonic (trophectoderm) development	Dispensable for most cell cycles in Drosophila and the mouse.
			$Dp2^{-/-}$	Not yet characterized	

[a] Many Drosophila genes have a large maternal contribution, and the phenotypes listed are at the stage of depletion of the maternal supply.
[b] Common mouse strains used for gene targeting (including C57Bl/6 and 129/sv) have an inactivating mutation in *cdk3*, therefore *cdk2* knockouts are also deficient in *cdk3*.

an yeast Cln-deficient strain, and thus was capable of substituting for the function of these cyclins in the G1-S phase transition in yeast. Mammalian Cyclin E mRNA, protein, and associated Cdk2(3) kinase activity peaks at late G1 phase and is rapidly degraded during S phase. As described earlier, in mammalian cultured cells, Cyclin E plays an essential role in G1 to S phase progression, and further studies have shown that downregulation of Cyclin E is crucial for the G1 arrest that must occur in terminally differentiating cells. Conversely, abnormal increases in expression of Cyclin E leads to premature entry of G1 cells into S phase and furthermore can lead to chromosome instability, one of the hallmarks of cancer.

The Drosophila homolog of *cyclin E*, *DmcycE* encodes two proteins with a common C-terminal and unique N-terminal regions. These two different Cyclin E variants are differentially expressed in proliferating cells during embryogenesis. *DmcycEII* mRNA is supplied maternally and is present during early embryonic division cycles, whereas *DmcycEI* mRNA is supplied zygotically and is expressed in all proliferating cells. Analysis of the *DmcycEI* promoter revealed the presence of multiple independent tissue and stage-specific regulatory elements, suggesting that *DmcycE* transcription is regulated by a variety of developmental cues. Drosophila Cyclin E interacts with the Drosophila homolog of the mammalian Cdk2 protein, Cdc2c, and is necessary and sufficient for the G1 to S phase transition. *DmcycE* loss-of-function mutants arrest in G1 of cycle 17 during embryonic development, due to the depletion of maternal supplies at this stage (see Table 1). Conversely, ectopic overexpression of DmcycE in G1-arrested cells drives these cells into a premature S phase. Furthermore, in Drosophila, overexpression of Cyclin E leads to defects in expression of morphogens and morphological movements during embryonic development, and in the eye imaginal disc, ectopic expression of Cyclin E disrupts normal pattern formation. Thus, Cyclin E is a critical regulator of the G1-S transition in Drosophila and its downregulation is important for normal development.

In mammals, there are two *cyclin E* genes, *Ccne1* and *Ccne2*. Recently, single and compound mutations of the *cyclin E* genes, and a knockout of *Cdk2* have revealed unexpected results (see Table 1). Mice singly deficient for *cyclin E1* or *E2* are viable with no apparent defects, with *cyclin* $E2^{-/-}$ males displaying decreased fertility indicating a specific requirement for Cyclin E2 in meiosis. Surprisingly, compound loss of *cyclin E1* and *E2*, results in a relatively late embryonic lethality at E10.5–E11.5 of development. By analysis of the tetraploid chimera, lethality at this stage was shown to be due to an extraembryonic requirement for *cyclin E* in the endoreplicating trophoblasts of the placenta. Provision of wild-type placenta to *cyclin* $E1^{-/-}$ $E2^{-/-}$ embryos resulted in survival to term of many embryos with the rest succumbing to cardiac abnormalities. Importantly, all other major organs examined appeared normal in *cyclin* $E1^{-/-}$ $E2^{-/-}$ embryos, indicating that Cyclin E activity is largely dispensable for normal mammalian development. However, a number of tissues are critically dependent on Cyclin E levels in the mouse. These included trophoblast giant cells required for placental function and megakaryocytes, both of which undergo repeated rounds of DNA synthesis without intervening mitoses (endoreplication) (see Sect. 2.7.2.2). These data highlight an important role for mammalian Cyclin E in driving the endoreplication cycles. Mouse embryonic

fibroblasts (MEFs) derived from the *cyclin E1*$^{-/-}$ *E2*$^{-/-}$ mutant mice, showed that *cyclin E* is dispensable for continual proliferation, but not for cell cycle reentry. Cell cycle reentry in the absence of Cyclin E activity resulted in defective DNA replication due to defects in the loading of the MCM protein complex onto DNA-replication origins (see Sect. 2.7.2).

Likewise, the analysis of Cdk2-deficient mice suggested that Cdk2 is dispensable for mitotic divisions and development (Table 1). *Cdk2*$^{-/-}$ mice are born viable with no gross anatomical or behavioral abnormalities; however, these mice are sterile due to defects in the meiotic cell cycle. Moreover, MEFs derived from these mice, proliferate normally in the absence of Cdk2. This is consistent with the results from the depletion of *cdk2* in human cancer cell lines. This surprising finding is unlikely to represent compensation by Cdk3, the other kinase bound by Cyclin E, as the mice used in these studies carry a predicted inactivating mutation in *Cdk3*. It is possible that Cdk1 can compensate for Cdk2, since Cyclin A/Cdk1 and Cyclin B/Cdk1 can drive cells through S phase and *Cdk2*$^{-/-}$ embryos contain unchanged levels of Cyclin A-associated kinase activity, presumably due to Cdk1. Therefore, Cyclin A/Cdk1 may compensate for S-phase functions normally mediated by Cyclin E/Cdk2 and Cyclin A/Cdk2 kinase. This is in contrast to the situation in Drosophila, where Cyclin E and Cdk2 are essential for cell cycle progression and normal development (Table 1). Interestingly, unlike the *cyclin E* knockout mouse phenotype, *Cdk2* mutants did not exhibit defects in the extraembryonic tissue, suggesting that Cyclin E may have Cdk2(3)-independent functions.

Mouse transgenic studies have shown that inappropriate expression of *cyclin E* can lead to tumorigenesis. Indeed, high levels of Cyclin E expression are associated with a broad spectrum of human malignancies, and in breast cancers, truncated versions of Cyclin E that are more stable and have increased associated kinase activity have been observed. Moreover, expression levels of Cyclin E often correlate with prognosis and the progression stage of human cancers, with higher levels associated with later stages of tumorigenesis.

2.2.1.3 **Cyclin D/Cdk4(6).** Cyclin D1 was also discovered as a gene capable of rescuing Cln-deficient yeast, suggesting that it can complex with the yeast Cdk, Cdc28, to drive the G1-S phase transition in yeast. As discussed earlier, in mammalian cells, Cyclin D is a family of three related proteins, D1, D2, and D3, which form a complex with Cdk4(6). D-type cyclins accumulate in response to mitogenic signals and have been proposed to provide the link between extracellular signaling pathways and the core cell cycle machinery.

In Drosophila, there is only one *cyclin D* and one *cdk4* homolog, and mutations have been now described in both genes (Table 1). Cyclin D-Cdk4 function is dispensable for survival, as flies that lack parental and zygotic Cdk4 function are semiviable. In addition, overexpression of Cyclin D-Cdk4 in embryos, has minimal effect on Cyclin E activity, suggesting that in Drosophila, Cyclin D has little role in titrating away inhibitors from the Cyclin E-Cdk2 complex. However, depending on the tissue or differentiation state, the role of Cyclin D-Cdk4 expression differs. In differentiating cells of the third instar larval eye imaginal disc, overexpression of Cyclin D-Cdk4 leads to increased cell growth (larger-sized cells), but in the proliferating cells of the wing disc, leads to coordinated cell growth and cell division.

In the mouse, the three D-type cyclins are expressed in a tissue-specific manner. Single knockouts of either *cyclin D* gene resulted in viable mice; however, hypoproliferative defects were observed in those tissues where the gene was maximally expressed (Table 1). Recently, mice have been generated that lack all D-type cyclins or Cdk4/6. Both *cyclin D*-deficient embryos and *cdk4/6*-deficient embryos survive until E15.5 of development, but display a severe anemia with megaloblastic features. Both *cyclin D*-deficient and $cdk4^{-/-}$ $cdk6^{-/-}$ fetal livers, show defects in multiple hematopoietic lineages. The similarity in phenotypes of the *cyclin D*-deficient and $cdk4^{-/-}$ $cdk6^{-/-}$ mice, indicate that the major function of Cyclin D in development is to activate Cdk4/6. Analysis of MEFs showed that Cyclin D and Cdk4/6 were not essential for cell cycle entry. However, Cyclin D-deficient and $cdk4^{-/-}$ $Cdk6^{-/-}$ MEFs were sensitive to loss of Cdk2 activity. Thus, while the majority of mouse tissues do not need Cyclin D or Cdk4(6), it appears that the loss of Cyclin D/Cdk4(6) can be compensated for by Cyclin E (or A)/Cdk2 complexes.

Transgenic mice overexpressing D-type *cyclins* show hyperplasia and increased incidences of tumors. Conversely, MEFs deficient in *cyclin D* or *Cdk4/6* were refractory to transformation by oncogenes. This oncogene-mediated transformation resistance also occurred with MEFs deficient in *cyclin E*, and to a lesser extent in Cdk2, suggesting that cells may require a certain Cdk threshold to enable transformation. Consistent with this, both Cyclin E and Cyclin D upregulation have been implicated in human cancers. Indeed, the oncogenes, *Prad1* (resulting in parathyroid adenoma) and *Bcl1* (resulting in B-cell lymphoma) are due to the translocation of the *cyclin D1* gene resulting in ectopic expression in parathyroid or B cells, respectively.

2.2.1.4 **Other cyclin-Cdks in G1-S progression.** There are several other classes of cyclins that are present in mammals that have less well-defined roles in G1-S phase regulation. These are Cyclin C, G, and F (discussed below). Other cyclin-Cdks have more general roles in the cell cycle, such as Cyclin H/Cdk7, which has Cdk activating kinase (CAK) activity and activates core cell cycle cyclin/Cdk5 during G1-S and G2-M phase by phosphorylating a critical threonine residue (T160 in Cdk2) (see Sect. 2.4.1). Cyclin H/Cdk7 also has a role in RNA polymerase II transcription, as does Cdk9 in association with T-type Cyclins and Cyclin K, and Cyclin C/Cdk8. Since these do not have specific roles in the G1-S phase transition, we will not discuss these further. Current knowledge of the role of Cyclin C, G, and F is summarized in the following.

Cyclin C was originally identified (along with Cyclin D and E) as a protein that when expressed in yeast was capable of rescuing a Cln-deficient strain, and has highest homology of all the mammalian cyclins to the Cln proteins. Cyclin C was also isolated from Drosophila by its ability to rescue the yeast *cln* mutant stain. Cyclin C associates with Cdk8 in both mammalian cells, and in Drosophila, and plays a role in RNA polymerase II transcription. Furthermore, Cyclin C/Cdk8 has been shown to phosphorylate specific transcription factors at their promoters, leading to their degradation via ubiquitin-mediated proteolysis (see Sect. 2.4.3). Recently, however, a complex between Cyclin C and Cdk3 has been observed and shown to play a role in passage from quiescence (G0) into the cell cycle. Indeed, Cyclin C/Cdk3 targets the same critical protein, as Cyclin D and

Cyclin E-Cdks, to mediate passage through G0-G1 (see Sect. 2.3).

Cyclin G was discovered as a target of the p53 transcription factor, which is a tumor suppressor that plays a critical role in DNA replication and DNA-damage checkpoint response (see Sect. 2.6). Further studies have shown that Cyclin G plays a role in negatively regulating the p53 pathway. Cyclin G has also been shown to promote cellular growth, and to form a complex with the protein kinase, GAK, which appears to play a role in modulating transmembrane receptor signaling pathways.

Cyclin F was discovered by its ability to rescue yeast mutants in Cdc4, which is a component of the S-phase ubiquitin-ligase complex, SCF (see Sect. 2.4.3). Cyclin F is closely related to Cyclin A, but also contains an F-box motif, which is a sequence present in Cdc4 that has a role in substrate recognition (see Sect. 2.4.3). Cyclin F expression is highest in S and G2 phases and is phosphorylated and rapidly degraded in mitosis. Recently, *cyclin F* (*cycF*) knockout mice have been generated, and show cellular defects suggesting a role in progression from G0 into S phase. While $cycF^{-/-}$ mice die at E10.5 due to defects in the proliferation of the chorionic trophoblast cells of the placenta, $cycF^{-/-}$ MEFs, although viable, are unable to reenter the cell cycle from quiescence (G0). In $cycF^{-/-}$ cells, the expression of Cyclin E was delayed, suggesting that Cyclin F may play a role in the control of Cyclin E expression; however, the precise role of Cyclin F in the progression from G0 into S phase remains to be determined.

2.2.2 Cks (Suc1, p13)

Another evolutionary conserved core protein present in the Cyclin/Cdk complex is Cks (also known as Suc1 or p13). Cks can promote the assembly and activation of yeast G1-S–cyclin/Cdk complexes *in vitro*. However, the function of Cks is not specific to the G1-S phase, and in yeast, appears to play a primary role in promoting mitosis through transcriptional regulation of an important gene, *cdc20*, which is required for proteolysis in mitosis. In mammalian cells, there are two homologs of Cks, Cks1, and Cks2, which play redundant roles in development. However, knockout of both genes in the mouse leads to early embryonic lethality, which precludes detailed analysis of specific cell cycle defects. Mammalian Cks1 also has a Cdk-independent role in promoting degradation of the cell cycle inhibitors, p27 and p130, via the SCF ubiquitin ligase (see Sect. 2.4.3), thereby promoting G1-S phase progression.

2.3 The Retinoblastoma-E2F Pathway – A Target of Cyclin/Cdks in G1-S Phase Progression

While much is known about the regulation of cyclin/Cdk activity, few targets of G1 cyclin/Cdk complexes have been described. In mammalian cells, the most extensively characterized target of cyclin/Cdk complexes is the retinoblastoma tumor suppressor (Rb) family of ''pocket proteins'', Rb, p107 and p130.

2.3.1 Rb Regulates the G1-S Restriction Point

The phosphorylation state of Rb proteins varies through the cell cycle, and is correlated with activity. Dephosphorylated Rb proteins are present in quiescent cells and cells in early G1, while phosphorylated forms of these proteins are present from late G1 until the end of mitosis. The growth inhibitory effects of the Rb family of proteins are associated with the hypophosphorylated forms that interact with

a family of transcription factors known as E2Fs. Hyperphosphorylated Rb proteins are unable to interact with E2Fs, allowing E2F-mediated activation of S phase and G1-S transition genes. Thus, the phosphorylation state of Rb proteins regulates the G1-S transition. Indeed, Rb is thought to define the *restriction point*: Once Rb becomes phosphorylated and inactivated, cells are committed to enter and complete a cell cycle driven through the E2F transcriptional program. E2Fs are required for the activation of genes important for the initiation and regulation of DNA synthesis such as *PCNA*, *RNR2*, *Cdc6*, *dihydrofolate reductase*, *DNA polymerase* α, and *thymidine kinase*, as well as genes required for the G1-S phase transition, such as *cyclin E*, *cyclin A*, and *cdk2*. In addition to being the main transcriptional controllers of G1 to S phase progression, E2Fs have now also been shown to regulate the expression of genes required for DNA repair, cell cycle checkpoint activation and maintenance and mitosis. Furthermore, E2Fs can also regulate genes involved in apoptotic signals as well as differentiation.

2.3.2 Current Model of Cell Cycle Control by Rb and E2F Family Complexes

E2Fs comprise a group of at least seven related proteins that can be divided into distinct subsets, on the basis of differences in both their transcriptional properties and their interaction with the Rb-family members, Rb, p107, and p130 (see Fig. 3). One subgroup consists of E2Fs that are potent transcriptional activators (E2F1, E2F2, E2F3a) while another subgroup behaves as transcriptional repressors (E2F3b, E2F4, E2F5, E2F6, E2F7). The *E2F3* locus gives rise to two protein isoforms (E2F3a and E2F3b) that differ only in their N-terminal region but have opposite transcriptional activities. With the exception of E2F7 that homodimerizes, binding of E2F moiety to one of two DP partners (DP1 or DP2) allows competent DNA binding to promoter regions of target genes at a consensus E2F binding site, TTTSSCGC (where S refers to C or G).

Extensive *in vitro* biochemical studies have provided a concise model for how various E2F/Rb complexes regulate cell cycle progression (see Fig. 4). Early in the cell cycle (G0 and G1), E2F4 and E2F5 (and presumably E2F3b) regulate transcriptional repression at E2F-dependent promoters by binding to p107 and p130, leading to the recruitment of a corepressor complex containing histone deacetylases (HDAC), histone methyltransferases (HMT), Sin3 and members of the SWI(SNF) family. At the G1-S transition, transcriptional repression is relieved through the phosphorylation of Rb-related proteins by cyclin-dependent kinases, which releases the ''repressor'' E2F complexes. This allows the ''activator'' E2Fs, E2F1, 2 and 3a, and coactivator complex that includes p300(CBP) to occupy the promoter and leads to transcriptional activation of E2F-dependent promoters. In this manner, E2Fs can participate in both the repression and activation of E2F-responsive genes, dependent on their association with Rb-family members. Although this model is well supported by chromatin immunoprecipitation (ChIP) studies, identifying the E2F species bound to promoters of E2F target genes through the cell cycle of *in vitro* cell lines, it must be noted that *in vivo* studies indicate that this model may be somewhat simplistic and the transcriptional properties for a given E2F may be modified depending on the developmental context (see Sect. 2.3.6).

In contrast to E2F1–5, E2F6 and E2F7 are not bound by Rb-family proteins and are therefore regulated differently. E2F6 does not contain an Rb-family

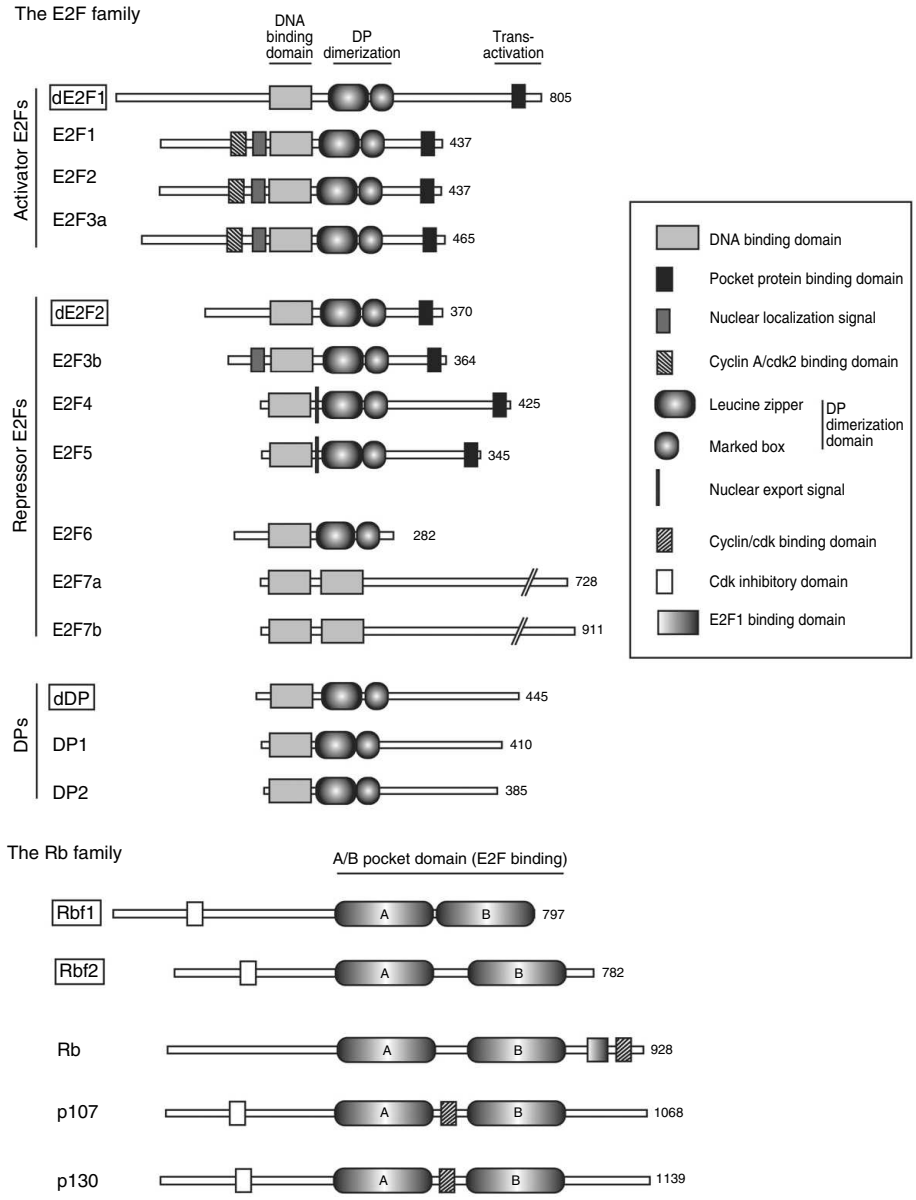

Fig. 3 Structure of the E2F, DP, and Rb family of proteins. The structure of the E2F, DP, and Rb-family members from mammalian cells and Drosophila are compared. Drosophila protein names are boxed.

binding domain and acts to repress transcription by recruiting the Polycomb group of chromatin-remodeling factors to promoters. Recent studies indicate that it may play a redundant role with E2F4 in regulating the G1-S and G2-M transitions.

E2F7 functions independently of a DP partner and of Rb-family members and is thought to repress transcription and cell cycle progression by competing with the activating E2F members at a subset of E2F promoters.

2.3.3 Regulation of Rb, E2F, and DP Function by Cdks

Rb has 15 consensus G1 cyclin/Cdk phosphorylation sites that are conserved among a wide variety of organisms. *In vitro*, human Cyclin D/Cdk4(6) and Cyclin E/Cdk2 are able to phosphorylate Rb at different sites, with neither being sufficient to phosphorylate all sites observed *in vivo*, indicating that both of these kinases are involved in the phosphorylation of Rb. Indeed, by selectively inhibiting Cdk2 or Cdk4(6) function, it has been shown that Cyclin D complexes are only able to partially phosphorylate Rb, and this phosphorylation is required for the action of Cyclin E/Cdk2 on Rb. These data have given rise to a model of sequential phosphorylation of Rb, initially by Cyclin D/Cdk4(6) followed by Cyclin E/Cdk2. There is also strong evidence that Rb is the only essential target of Cyclin D/Cdk complexes, as the G1 arrest induced by injection of anti-Cyclin D antibodies is dependent on wild-type Rb function. By contrast, Cyclin E is required for entry into S phase in Rb-deficient cells, indicating that Cyclin E/Cdk2 has additional essential targets in the G1 to S phase transition. Although these additional targets are likely to include the Rb-related proteins p107 and p130, Cyclin E is still required for the G1 to S phase transition after collective inactivation of all pocket proteins using the SV40 DNA tumor virus large T antigen. Pertinent to this, activated Cyclin E/Cdk2 allows firing of DNA-replication origins and coordinated centrosome duplication (see Sect. 2.7), and regulates the activity of both chromatin-remodeling factors and the NPAT transcription factor, which is required for the expression of histone genes. A role for other Cdk complexes has also been proposed in regulating Rb function. Overexpression of Cyclin A in cell culture leads to phosphorylation of Rb, and Cyclin A/Cdk2 can phosphorylate Rb *in vitro*. It remains unknown, however, whether phosphorylation of Rb by Cyclin A/Cdk2 is important for Rb inactivation. Finally, recent studies have shown that Cyclin C/Cdk3 can also phosphorylate Rb in the transition from G0 into G1 (see Sect. 2.2.1.4).

Cdk phosphorylation can also regulate E2F/DP transcriptional activity directly. Cyclin E/Cdk2 has been shown to phosphorylate E2F5, resulting in the recruitment of the p300(CBP) family of coactivators to promoters, thereby stimulating transcription and cell cycle progression. Importantly, phosphorylation of the DP subunit of E2F by CyclinA/Cdk2 in S phase leads to loss of E2F heterodimer DNA binding activity and is thought to be one of the major mechanisms by which E2F transcriptional activity is switched off following the G1-S transition.

2.3.4 Target Gene Regulation by E2F and Rb

As indicated earlier, hypophosphorylated Rb, in a complex with E2F and DP, acts to repress gene transcription by recruiting global transcriptional repressors, such as HDACs and chromatin-remodeling complexes to E2F-target promoters (see Fig. 4). Phosphorylation of Rb promotes its release from E2F/DP, and replacement of the HDACs with histone acetylases such as p300(CBP) allowing the activation of E2F-responsive promoters. To date, the regulation of the ''classical'' E2F target genes *cyclin E1* and *cyclin A1* have been the

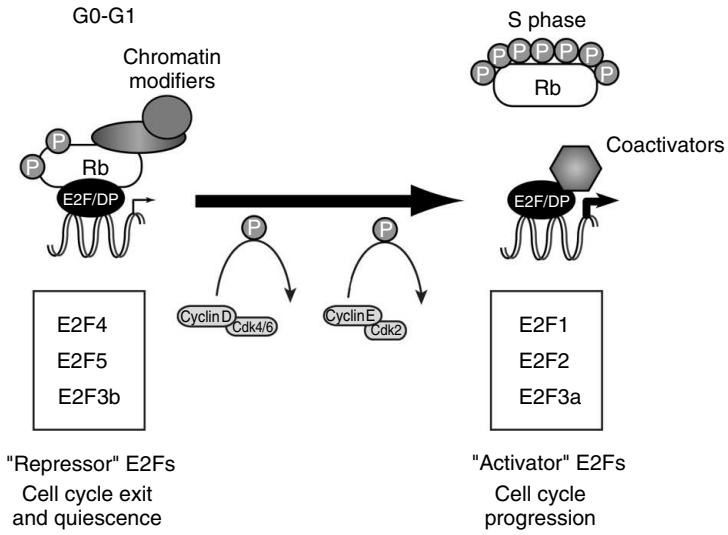

Fig. 4 E2F, DP, and Rb family of proteins in transcriptional regulation of S-phase genes. Repressor E2F proteins act with Rb-family members and chromatin-remodeling factors to repress S-phase genes at the G0-G1 phase. In the G1-S phase transition, Rb-family proteins are phosphorylated and inactivated by Cyclin/Cdks. Activating E2Fs then bind to S-phase gene promoters, along with coactivators, to transactivate transcription. Not shown are E2F6 and E2F7 proteins, which are thought to mediate transcriptional repression in G0-G1 (and hence are also classed as repressor E2Fs) but do not bind to and are not regulated by Rb and family members.

most thoroughly studied. In mammalian cells, *cyclin E1* transcription is activated when Rb is hyperphosphorylated. The human *cyclin E1* promoter contains an E2F binding site, and at this site a complex of E2F4, Rb, Brg1 (SWI or SNF) chromatin-remodeling complex and HDAC has been detected. Phosphorylation of Rb by Cyclin D/Cdk4 disrupts the association with HDAC, leading to the expression of *cyclin E1*. *Cyclin A1* transcription is also repressed by an E2F4/Rb/Brg1/HDAC complex, but this complex is still active upon the loss of HDAC by Cyclin D/Cdk4 mediated phosphorylation of Rb. Since Cyclin E/Cdk2 is known to phosphorylate and inactivate Brg1, only when Cyclin E/Cdk2 levels increase in late G1 phase can repression at the *cyclin A1* promoter be relieved.

Recently, microarray expression profiling of mammalian E2F targets together with ChIP studies, have revealed that in addition to regulating G1-S transition and S-phase genes, E2F also regulates genes involved in the DNA damage checkpoint, DNA repair, chromatin assembly or condensation, chromosome segregation, and the mitotic spindle checkpoint, suggesting that E2F activity is important for both G1-S and G2-M phase progression. Likewise in the Drosophila system (see below), expression profiling of E2F-Rb pathway targets has revealed both G1-S and G2-M targets, but unexpectedly also showed that different specific E2F-Rb complexes repress the expression of target genes required for differentiation that are transcribed in a developmentally regulated,

rather than a cell cycle–regulated manner. This result provokes speculation that in mammalian cells, the E2F-Rb pathway may also not be exclusive to the regulation of cell cycle genes. Consistent with this hypothesis, genome-wide analysis in mammalian cells have identified a number of E2F targets involved in differentiation and development including *HOX* cluster genes, tissue-specific transcription factors and growth factors such as *BMP2* and *TGFα*.

2.3.5 Functional Analysis of Rb, E2F, and DP in Drosophila

The study of Drosophila has been key to understanding the complex interplay between E2F, DP, and Rb function due to its reduced complexity. Drosophila homologs of the retinoblastoma protein (RBF1 and RBF2), two E2F proteins (dE2F1 and dE2F2), and one DP (dDP) protein have been identified (see Fig. 3). Drosophila RBF1 and RBF2 are equally similar to the mammalian Rb, p107, and p130 proteins. Similar to mammalian Rb-family proteins, RBF1 is phosphorylated by Drosophila Cyclin E/Cdk2, which is important for its inactivation. dE2F1, a potent transcriptional activator, is specifically bound by RBF1, which is required to prevent E2F1-dependent transcription of S-phase genes. Conversely, RBF2 binds exclusively to dE2F2, which functions as a transcriptional repressor. RBF1 can also bind to dE2F2; however, dE2F2 can function as a repressor independent of RBF1, since inactivation of RBF1 by expression of Drosophila Cyclin E/Cdk2 does not override repression by dE2F2. Interestingly, microarray analysis suggest that RBF1 and dE2F1 coordinately regulate expression of genes involved in cell cycle progression, while RBF2 and dE2F2 repress a variety of tissue-specific genes involved in differentiation. In the absence of dE2F1, dE2F2 occupies dE2F1-regulated promoters. The defects that occur in *dE2F1* mutants are therefore due to unchecked activity of the dE2F2 repressor since they can be suppressed by mutating *dE2F2*.

Drosophila embryos lacking maternal and zygotic *RBF1* expression show ectopic expression of the dE2F target genes *PCNA* and *RNR2*. Despite the ectopic expression of *PCNA* and *RNR2*, epidermal cells of *RBF1* mutant embryos appear to transiently arrest in G1, although these cells subsequently enter ectopic S phases. Thus, RBF is required for the maintenance of the G1-arrested state. Mutant analysis of Drosophila *dE2F1* and *dDP* showed that dE2F1 is required for the G1-S transcriptional program, as embryos homozygous for null mutations in *dE2F1* or *dDP* do not express dE2F target genes such as *RNR2* and *PCNA*. In some tissues in *dE2F1* or *dDP* mutants, transcription of *cyclin E* was also affected, although Cyclin E/Cdk2 function still remained. Thus, while dE2F1 is required for normal levels of *cyclin E* expression in some tissues, dE2F-independent mechanisms for *cyclin E* transcription also exist. Consistent with this finding, there is evidence that *cyclin E* transcription is regulated by developmental signals in many tissues (see Sect. 2.5).

Surprisingly, analysis of Drosophila lacking all dE2F family members (dE2F1 and dE2F2), suggests that dE2F regulation is not required for cell proliferation (Table 1), raising questions as to the function of dE2F in cell cycle control. Recent studies in Drosophila have addressed this issue by revealing a striking role for dE2F in G1-S and G2-M phase timing. It was shown that perturbations to progression through either G1-S or G2-M were compensated for by adjustment of

the time spent in the alternate phase of the cell cycle. dE2F1/dDP was important for this coordination, via transcriptional upregulation of *cyclin E* in G1-S and of the G2 regulator, *cdc25* (*string*) (see Sect. 2.4.1) in G2-M. Conversely, dE2F protein levels are downregulated in S-phase cells by the SCF complex using the F-box protein, Slimb, via phosphorylation by Cdk1 and Cdk2 (see Sect. 2.4.3). As mammalian E2Fs have also been shown to regulate genes important for G1-S and G2-M progression, analogous cell cycle compensation mechanisms may operate in mammalian tissues.

2.3.6 Functional Analysis of Mammalian Rb, E2F, and DP: Lessons from Mutant Mice

Although biochemical approaches originally identified E2F and Rb proteins in mammalian cells, genetic studies in Drosophila have been key to the formulation of hypotheses, as to the mechanism of action and diversity of E2F and Rb function. Genetic studies in mammalian systems have confirmed current views but also revealed unexpected roles for Rb and E2F families in development and tissue homeostasis (Table 1).

2.3.6.1 **Analysis of Rb-family single and compound mutant mice.** Rb-deficient mice die at E13.5–E15.5 of development with defects in ocular lens development, neurogenesis, and erythropoiesis (see Table 1). Analysis of these tissues revealed extensive ectopic proliferation, abnormal differentiation, and apoptosis consistent with the proposed role of Rb in controlling the *restriction point* and cell cycle exit during terminal differentiation. However, subsequent analysis of mice chimeric for Rb-deficient cells indicated that *Rb*-null cells could contribute to the majority of tissues of these animals with an apparent absence of defects in Rb-deficient tissues. These studies therefore suggested that the neuronal and erythroid phenotype resulting from loss of Rb function may not be cell intrinsic. Consistent with this notion, recent analysis has shown that these defects are in part due to a role for Rb in placental development. As observed for *cyclin E*, Rb as well as E2F3 and DP1 play an important role in controlling the endoreplication of the extraembryonic trophoblast cells (see Sect. 2.7.2.2). Provision of a wild-type placenta to Rb-deficient embryos largely rescued the embryonic defects, indicating that many of the *Rb*-null cell phenotypes are noncell intrinsic. Rb, like Cyclin E, is also required for megakaryocyte maturation, another cell type that undergoes polyploidization during differentiation. This is consistent with studies in Drosophila, where Rbf, dE2F1, and dDP, function together at DNA-replication origins to regulate endoreplication of *chorion* genes in Drosophila follicle cells (see Sect. 2.7.2.2).

Although placental dysfunction in *Rb*-null embryos can account for their lethality, conditional deletion of Rb specifically in erythroid cells or neuronal cells nevertheless indicates that Rb is required in a cell-intrinsic manner for cell cycle exit and differentiation of these cell lineages. For example, acute loss of Rb in erythroid cells leads to enucleation defects, ectopic proliferation, and accumulation of cells in G2-M presumably due to engagement of DNA damage checkpoint. Similarly specific deletion of Rb in the central nervous system (CNS) *in vivo* results in inappropriate S-phase entry. However, in contrast to the *Rb*-null embryo situation, no apoptosis is observed in the CNS. The non-cell intrinsic apoptosis observed in *Rb*-null embryos has therefore been proposed to be a

direct result of the hypoxic environment caused by deficient placental function of *Rb*-null embryos. Using similar tissue-specific deletion of Rb approaches *in vivo*, a requirement for Rb has now been observed for the proper development of a wide variety of additional tissues including, skin, breast, lung, and muscle.

Similar to Rb, loss-of-function mutations in the mouse have indicated a requirement for p107 and p130 in cell cycle exit and differentiation. Indeed, although individual loss of p107 or p130 in the mouse result in viable and mostly normal adults, compound loss of p107 and p130 has revealed an important and overlapping role for these proteins in bone, and more recently, in skin development. p107, p130-doubly null mice die shortly after birth from unknown causes, but showed decreased limb size associated with defective endochondrial bone development and deregulated chondrocyte proliferation. Similarly, loss of p107 and p130 in skin epithelium results in impaired terminal differentiation and overproliferation of interfollicular keratinocytes *in vivo*. The partial redundancy of p107 and p130 in development has also been observed for Rb. Acute or chronic loss of Rb results in upregulation of p107 protein levels and embryos generated with a compound loss of p107 and Rb, or p130 and Rb, show similar phenotype to *Rb*-null embryos, but die two days earlier. Although animals deficient in all three Rb-family members have not yet been generated, the analysis of triple-deficient cells show them to be unresponsive to G1 arrest following DNA damage or growth-factor withdrawal and *in vivo* fail to differentiate and to exit the cell cycle.

In view of their role in controlling cell cycle exit and linking growth signals to the cell cycle, it may be expected that mutations in Rb-family proteins would lead to deregulated proliferation and predispose to tumor formation. Indeed, loss or inactivation of Rb is a frequent event in human tumors. In contrast, p130 is less frequently lost and p107 inactivation has not been reported. $Rb^{+/-}$ mice develop tumors of endocrine origin including pituitary, thyroid, and adrenal medulla tumors. Although loss of p107 or p130 alone has no effect on tumor susceptibility, combined deficiency of Rb and p107 causes retinoblastoma in the mouse indicating that these proteins partially overlap in tumor suppression. Importantly, tumor susceptibility in $Rb^{+/-}$ mice is thought to be in part a result of deregulated E2F activity as loss of E2F1, E2F3, or E2F4 can suppress tumorigenesis in $Rb^{+/-}$ mice. Finally, although in this chapter we have focused on the cell cycle roles of Rb family members related to regulation of E2F function, it must be noted that many studies have described non-E2F mediated roles for Rb, in particular in the control of differentiation, senescence and apoptosis. In the case of differentiation, Rb has been described to bind and regulate a number of tissue-specific transcription factors such as MyoD in muscle cells, CBFA1 in bone lineage cells, and C/EBPα in adipose tissue, and by so doing directly regulate the differentiation programs of these lineages. It is still unclear at this stage to what extent these other functions of Rb-family members contribute to tumour suppression or the developmental phenotypes of Rb-family mutant animals.

2.3.6.2 **Analysis of E2F/DP family single and compound mutant mice.** The presence of multiple mammalian E2F and DP family members has made analysis of their role in development complex due to issues of redundancy (see Table 1). Nevertheless,

analysis of mice singly and compound mutant for E2Fs have provided novel and often surprising insights into the functional requirement of these proteins in development and tumorigenesis.

Mice deficient for E2f1 are viable and fertile and show excessive T-cell production and testicular atrophy. In addition, and paradoxically in view of its proposed role in driving proliferation, *E2f1*$^{-/-}$ mice show increased tumor predisposition in aged mice. E2f1 has been shown to be able to induce apoptosis (cell death) and hence this property may provide an explanation for the increased tumor predisposition of *E2f1*$^{-/-}$ mice. Alternatively, recent experiments have also implicated E2f1 in regulating the DNA damage response pathway therefore predisposing *E2f1*$^{-/-}$ mice to acquire somatic mutations. *E2f2*$^{-/-}$ mice are viable and fertile; however, they develop late onset autoimmune disease that is thought to result from decreased activation threshold of *E2f2*$^{-/-}$ T cells. In this context, and contrary to its proposed role in driving proliferation, E2f2 has been proposed to act as a transcriptional repressor of genes required for S phase, in particular, E2f1. In contrast, E2f3 is required for normal development with the majority of E2f3-deficient mice dying *in utero* and the adult survivors succumbing to heart failure by 12 months of age. Compound E2f mutant mice have also revealed a level of redundancy between E2f1, E2f2, and E2f3. *E2f1*$^{-/-}$ *E2f2*$^{-/-}$ mice display defects in multiple hematopoietic lineages including B, T, and erythroid cells resulting in megaloblastic anemia. These defects appear to be due to impaired S-phase progression and decreased expression of E2F targets such as *cyclin A2*. In addition, compound loss of E2f1 and E2f2 leads to increased incidence of T-cell tumors as well as nonimmune related diabetes. Finally, compound loss of E2f2 or E2f1 and E2f3 exacerbates the respective developmental defects of each E2F mutant mouse.

In contrast to the ''activating'' E2F family members, loss of function of the ''repressor'' E2f3, E2f4, E2f5, or E2f6 appears to give rise to differentiation related phenotypes. *E2f4*$^{-/-}$ mice show growth retardation and die neonatally due to upper respiratory tract infections. They display fetal megaloblastic anemia and defects in gut development. Of note is the fact that recent analysis of the erythroid defect of *E2f4*-deficient mice has indicated an unexpected role for E2f4 in promoting (rather than inhibiting) transcriptional activation and cell proliferation of the erythroid lineage. Loss of E2f5 results in perinatal death due to hydrocephaly in what is thought to be a non-cell cycle related E2f5 function. E2f5 is highly expressed in the choroid plexus and has been proposed to regulate cerebral spinal fluid (CSF) protein secretion. Finally, *E2f6*$^{-/-}$ mice are viable; however, they show homeotic transformation of their axial skeleton reminiscent of mice with mutations in the Polycomb group of chromatin-remodeling proteins. This is consistent with the known ability of E2F6 to recruit Polycomb group proteins to direct repression of target genes and suggests a function for E2F6 in the direct regulation of developmental transcriptional programs.

In summary, the *in vivo* analysis of E2F function in mouse models, suggest that the convenient classification of E2Fs into activating and repressive E2Fs may be oversimplistic. E2F function will differ depending on cellular context and the expression of other E2Fs and Rb-family members. Although in many cases, E2Fs and Rb-family members appear to regulate cell cycle progression, in particular, the G1-S transition, it is also increasingly

clear that they can also regulate functions as disparate as apoptosis, DNA damage repair, differentiation, and developmental cues. It will therefore be important to conduct biochemical, functional, and gene expression analysis in specific tissues and cell lineages to obtain a thorough perspective of the function and crosstalk of these proteins families in the regulation of cell cycle progression and differentiation.

2.4 Regulation of G1-S Cyclin/Cdk Activity

In addition to Cdk activation by the binding of a cyclin, cyclin/Cdk activity is also regulated by phosphorylation, the binding of inhibitory proteins and proteolysis of the cyclin subunit.

2.4.1 Regulation of Cdk Activity by Phosphorylation

Two modes of phosphorylation have been documented in the regulation of cyclin/Cdk activity (see Fig. 5). The first of these modes of phosphorylation is stimulatory while the second is inhibitory. Stimulatory phosphorylation of the Cdk occurs on a critical threonine residue of the Cdk (Thr160/161 for Cdk2) in a region termed the *T-loop*, by CAK. CAK itself is composed of a cyclin/Cdk complex, Cyclin H/Cdk7 and a ring-finger protein, Mat1. CAK phosphorylation of Cdks is important to increase the binding affinity of the cyclin to Cdk and to increase the kinase activity. As described earlier (Sect. 2.2.1.4), analysis of the Cdk7 complex may be complicated as a result of its expected role in RNA polymerase II transcription. However, analysis of *Mat*1 mutant mice revealed defects in cell proliferation of embryonic cells and impaired endoreplication of extraembryonic trophoblast cells, but mutant cells did not show any apparent defects in general transcription. Thus, *in vivo* it appears that the primary role for mammalian Cyclin H/Cdk7/Mat1 complex is as a CAK, rather than in general transcriptional regulation. In Drosophila, the Cyclin H/Cdk7 complex is conserved and has CAK activity toward Drosophila Cdk1 and human Cdk2 *in vitro*. Drosophila temperature-sensitive *cdk7* mutants display defects in mitosis; however, the ovarian endoreplication cycles (see Sect. 2.7.2.2) were not affected. Thus, in Drosophila, the importance of Cdk7 in G1-S regulation is unclear. In

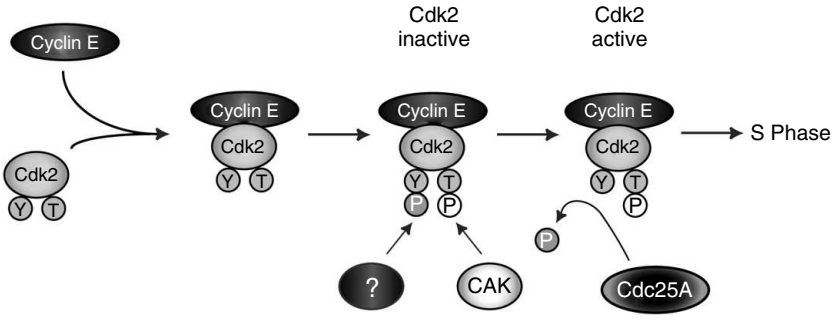

Fig. 5 Regulation of Cyclin/Cdk2 activity by phosphorylation. Mammalian Cyclin E/Cdk2 is regulated by two modes of phosphorylation. Phosphorylation at Thr160 on Cdk2 by CAK is required for activation, while phosphorylation at Tyr15 on Cdk2, by an unknown kinase, fixes Cyclin E/Cdk2 in an inactive state. It is only after the Cdc25A phosphatase is upregulated and dephosphorylates the Tyr15 of Cdk2 that Cyclin E/Cdk2 is activated.

contrast to the mouse studies, analysis of Drosophila *cdk7* mutants revealed defects in RNA polymerase II transcription. Taken together, these studies in Drosophila, suggest that Cyclin H/Cdk7/Mat1 complex may have roles as a CAK and in transcription in the fly.

The second mode of control of Cdk activity is through inhibitory phosphorylation. Inhibitory phosphorylation has been well documented for the mitotic Cdk, Cdk1, by the Wee1 kinase. Wee1 phosphorylates tyrosine and threonine residues (Tyr15, Thr14) on the N-terminus of Cdk1, which prevents cyclin/Cdk kinase activity. Removal of these inhibitory phosphates on Cdk1 by the Cdc25 phosphatase can be a rate-limiting step for entry into mitosis. In mammalian cells, the G1-S Cdks, Cdk2, and Cdk4, are also phosphorylated on the N-terminal tyrosine (Tyr15 and 17, respectively), which has been shown to be inhibitory to their activities. There are three Cdc25 phosphatases in mammalian cells, but Cdc25A is thought to be the major Cdc25 required for G1-S progression. Cdc25A is specifically expressed in late G1-S cells and is able to accelerate G1-S progression when ectopically expressed by dephosphorylating Cyclin E/Cdk2. Drosophila also has homologs of Wee1 and Cdc25, and studies of the Drosophila homolog of Cdc25, String, have shown that it is essential and rate limiting for the G2-M phase transition during Drosophila development. However, in Drosophila, this regulation does not extend to the G1-S Cdk, Cdk2, since mutations of the Cdc25/Wee1 regulatory site in Drosophila Cdk2 do not impair Cdk2 function in Drosophila.

2.4.2 Regulation of G1-S Cyclin/Cdk Activity by Cdk Inhibitors

In mammalian cells, the activity of cyclin-Cdk complexes is negatively regulated by direct interactions with proteins called Cdk inhibitors (Ckis). These proteins fall into two families on the basis of their structural and functional properties: INK4 family ($p15^{INK4B}$, $p16^{INK4A}$, $p18^{INK4C}$, $p19^{INK4D}$) and the CIP(KIP) family ($p21^{CIP1}$, $p27^{KIP1}$, $p57^{KIP2}$). The INK4 (inhibitor of Cdk4) class of proteins are composed of multiple ankyrin repeats, and bind Cdk4(6) preventing it from associating with Cyclin D, thereby preventing this complex from promoting G1-S phase progression (Fig. 6). The CIP(KIP) family of Cdk inhibitors act more broadly to inhibit the kinase activity of Cyclin E/Cdk2 and Cyclin A/Cdk2. Consistent with CIP(KIP)-family proteins inhibiting G1 Cyclin/Cdk activity, overexpression of any member of this family results in G1 phase arrest of cultured cells. Paradoxically, CIP(KIP) family play a dual role, since they can also act as positive regulators of Cyclin D/Cdk4 by stabilizing the formation of the Cyclin D/Cdk4 complex.

In Drosophila, there are no obvious INK4-family members and just a single CIP(KIP)-family protein, Dacapo (Dap). Dap is expressed at low levels in proliferating cells and is transiently expressed at high levels as cells exit from the mitotic cycle, consistent with a role in cell cycle arrest prior to terminal differentiation. Like mammalian CIP(KIP)-family proteins, Dap interacts with Cyclin E/Cdk2 *in vivo*, and is able to inhibit Cdk2-associated kinase activity *in vitro*. It is not currently known whether Dap also interacts with Cyclin D complexes. However, Dap does not inhibit Cyclin A-associated kinase activity, consistent with the data that Drosophila Cyclin A associates exclusively with Cdk1, and not Cdk2. Unlike mammalian inhibitors, which are not essential for viability, mutations in *dap* result in lethality. Epidermal cells of embryos

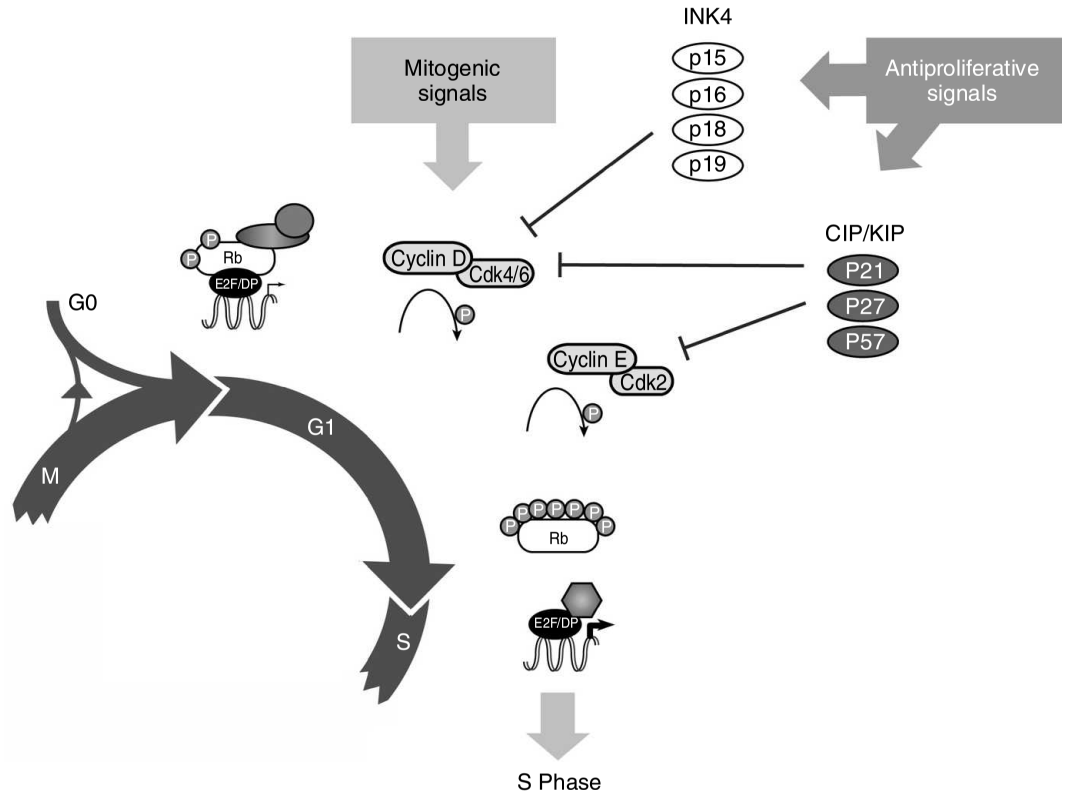

Fig. 6 Regulation of Cyclin/Cdk activity by Cdk inhibitors. Mitogens (such as EGF) lead to upregulation of Cyclin D expression, which acts to phosphorylate and inactivate Rb allowing G1-S phase progression. Antiproliferative signals (such as TGFβ) induce the expression of Cdk inhibitors (Ckis) of the $p16^{INK4A}$ and $p21^{CIP1}$ ($p27^{KIP1}$) families. $p16^{INK4A}$ family members act to specifically inhibit Cyclin D/Cdk4(6), while $p21^{CIP1}$ ($p27^{KIP1}$) proteins act more generally to block Cyclin D/Cdk4(6) and Cyclin E/Cdk2.

homozygous for mutations in *dap* undergo an additional cell cycle during embryogenesis, indicating that Dap is required for the establishment of the G1 arrest normally seen in these cells. In addition, ectopic expression of *dap* is sufficient to induce G1 arrest, showing that Dap is clearly required for timely exit from the cell cycle during Drosophila development.

Analyses of mice that are deficient for CIP(KIP)–family proteins indicate an important role for these Ckis in regulation of G1 progression and cell cycle exit *in vivo* (see Table 1). Ablation of $p27^{KIP1}$ in the mouse results in increased body size, overgrowth of organs, retinal dysplasia, female sterility, and pituitary and parathyroid tumors, consistent with a role in controlling proliferation during organ development. In contrast, mice deficient in $p21^{CIP1}$ are viable and normal and do not show increased tumor predisposition. Further analysis, however, has revealed a role for $p21^{CIP1}$ in hematopoietic stem cell maintenance, with loss of $p21^{CIP1}$ resulting in increased cycling of hematopoietic stem cells leading to exhaustion of the stem cell pool and eventually to hematopoietic failure. In mammalian cell culture, $p21^{CIP1}$ has been implicated in muscle cell differentiation. The transcription factor MyoD activates the expression of $p21^{CIP1}$, in addition to inducing the transcription of muscle-specific genes. Although the induction of $p21^{CIP1}$ was presumed to induce cell cycle arrest required for muscle differentiation, $p21^{CIP1}$ knockout mice do not show any muscle differentiation defects. Thus, $p21^{CIP1}$ does not play a critical role in muscle differentiation *in vivo*.

While most Ckis are not required for viability, loss of $p57^{KIP2}$ leads to neonatal death and severe developmental defects with phenotypic characteristics similar to the human disease, Beckwith–Wiedemann syndrome. These include cleft palate, defects in gut development, proliferative defects in the lens, and impaired cell cycle exit, during chondrocyte differentiation resulting in defective bone formation. These endochondrial bone development defects are very similar to those observed in mice compound mutant for the Rb-family members, p107 and p130. Likewise, compound loss of $p27^{KIP1}$ and $p57^{KIP2}$ gives rise to lens and trophoblast defects remarkably similar to that seen in Rb-deficient mice and compound loss of $p21^{CIP1}$ and $p57^{KIP2}$ result in deregulated proliferation and defective differentiation of skeletal muscle, again similar to that observed in Rb-deficient skeletal muscle. As Rb-family proteins are one of the primary targets of G1-S Cdks (see Sect. 2.3.3), the phenotypic similarities highlight a role for the CIP(KIP) family of Ckis in the regulation of Rb, p107, and p130 activity *in vivo*.

In contrast to the CIP(KIP) family, mutations in INK4 family members, primarily $p16^{INK4A}$ and $p15^{INK4B}$, have been consistently reported both in mouse and human tumors. The generation and analysis of single and doubly deficient mice for individual INK4 family members has increased our understanding of how these genes may be important in development and tumorigenesis (Table 1). Loss of $p15^{INK4B}$ results in lymphoproliferative disorder as well as small increased susceptibility to tumor development, primarily angiosarcomas. Because the INK4A locus also encodes the overlapping gene for the $p19^{ARF}$ tumor suppressor (see Sect. 2.6), it is only recently that the specific role of $p16^{INK4A}$ has been able to be tested *in vivo* by the generation of a mouse mutant for $p16^{INK4A}$, but retaining functional $p19^{ARF}$ protein. Only $p16^{INK4A}$ deficient mice are born viable

and normal; however, they develop a range of tumors including soft tissue sarcomas, lymphomas, and melanomas. In addition, $p16^{INK4A}$ deficient mice show thymic hyperplasia and T-cell hyperproliferation following stimuli consistent with a role in regulating cell cycle entry. Mice deficient for $p18^{INK4C}$ exhibit phenotypes similar to $p27^{KIP1}$-deficient mice including enlarged organs, tissue hyperproliferation, and a variety of tumors, including pituitary adenomas. Furthermore, $p18^{INK4C-/-}$ mice exhibit lymphoproliferative disease as well as epithelial proliferation in the kidney leading to the formation of cysts. Cyst formation is exacerbated in mice mutant for both $p18^{INK4C-/-}$ and $p15^{INK4B-/-}$, indicating some level of redundancy for these Ckis in epithelial tissues. Finally, loss of $p19^{INK4D}$ gives rise to viable mice; however, they develop age-related testicular atrophy and progressive hearing loss. The hearing loss is due to aberrant cell cycle reentry of sensory hair cells in the organ of Corti consistent with a role for $p19^{INK4D}$ in maintaining the postmitotic state. Redundant roles for $p19^{INK4D}$ and $p18^{INK4C}$ have been established in spermatogenesis, as compound loss of $p19^{INK4D}$ and $p18^{INK4C}$ enhances the $p19^{INK4D-/-}$ mice testicular defects, now resulting in sterility. The loss of fertility is primarily due to delayed exit of spermatogonia from the mitotic cycle, leading to apoptosis and decreased spermatocyte production.

The analysis of mouse models for INK4 and CIP(KIP) CDK inhibitors have revealed a large level of redundancy built into the mechanism required to maintain cells in quiescence as well as cell cycle progression *in vivo*. However, all experiments to date have demonstrated a requirement for these Cdk inhibitors for normal development, tissue homeostasis, and tumor suppression.

2.4.3 Regulation of G1-S by Ubiquitin-mediated Proteolysis

Protein degradation plays an important role in the G1-S phase transition. An ubiquitin ligase (E3) known as the SCF (Skp1/Cullin/F-box protein) complex, targets both Cdk inhibitors and cyclins to ubiquitin-mediated degradation (see Fig. 7). The catalytic core components of the SCF include Skp1, Cul1, and Rbx1, which assemble with a variety of substrate specific binding proteins known as F-box proteins to transfer ubiquitin (a 76-residue protein) onto substrates. Phosphorylation of targets, leads to recognition by the SCF complex and subsequent action of a ubiquitin-conjugating enzyme (E2), followed by a ubiquitin-activating enzyme (E1) to promote the addition of ubiquitin-residues to the substrate, thereby tagging it for degradation by the 26S Proteasome.

2.4.3.1 Regulation of Cki proteolysis by the SCF complex. The Cdk inhibitor $p27^{KIP1}$ is targeted for ubiquitin-mediated proteolysis by the SCF, after it is phosphorylated by Cyclin E/Cdk2. The F-box protein, Skp2, is important for recognizing phosphorylated $p27^{KIP1}$. Skp2 is synthesized specifically at the G1-S phase boundary, as is Cyclin E. This enables active Cyclin E/Cdk2 complexes (that are free of $p27^{KIP1}$) to accumulate, to phosphorylate $p27^{KIP1}$, and then Skp2-SCF mediated degradation of $p27^{KIP1}$, allowing a burst of Cyclin E/Cdk2 activity in cells committed to entering S phase. Skp2 also requires the small Cdk-binding protein, Cks1 (see Sect. 2.2.2), to bind to $p27^{KIP1}$ as well as some other substrates, such as the Rb-family member p130. The Cdk inhibitor $p21^{CIP1}$ is also ubiquitinated by Skp2-SCF upon phosphorylation at the G1-S phase transition; however, $p21^{CIP1}$

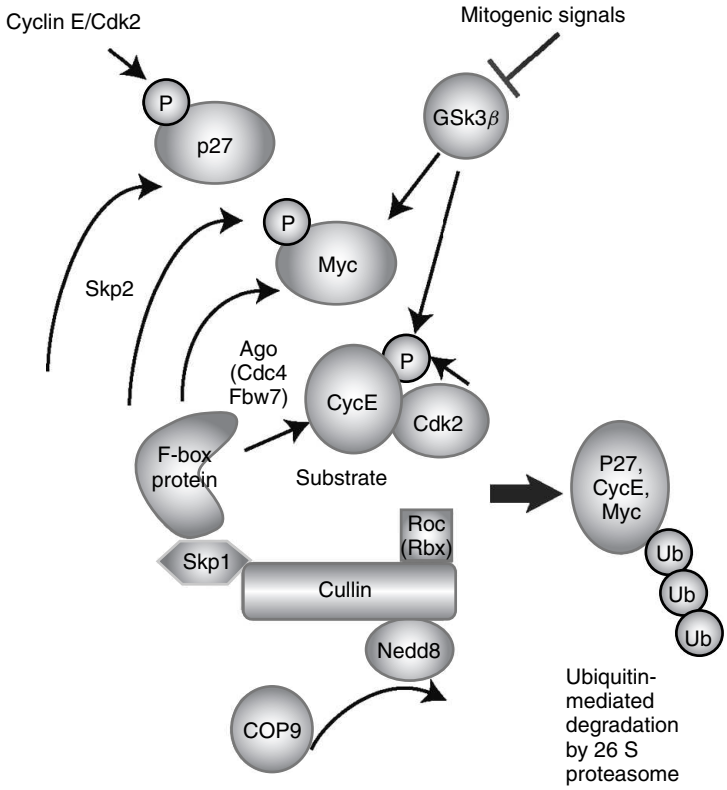

Fig. 7 Regulation of the G1-S phase by the SCF. The ubiquitin–ligase complex, SCF (composed of Skp1, Cullin, Rbx1, and an F-box protein) recognizes phosphorylated targets and ubiquitinates them, tagging them for ubiquitin-mediated degradation by the 26S proteosome. The Cullin in the SCF is modified by a ubiquitin-like protein, Nedd8, and cyclic removal of Nedd8 by the COP9 signalosome is required for SCF activity. The F-box, Skp2 (together with Cks1, not shown), targets phosphorylated $p27^{KIP1}$, which is phosphorylated by Cyclin E/Cdk2. SCF-Skp2 is also important in basal ubiquitin-mediated degradation of Myc. SCF-Fwb7(Ago) targets phosphorylated Cyclin E and Myc for ubiquitin-mediated degradation. Cyclin E is phosphorylated by the associated Cdk2 kinase. GSK3β also phosphorylates Cyclin E and Myc, tagging them for recognition by SCF-Fwb7(Ago). Mitogen signaling leads to the inactivation of GSK3β enabling progression from G1 into S phase.

can also be degraded by the proteasome via an ubiquitin-independent mechanism.

By contrast, the INK4 family of inhibitors are degraded throughout the cell cycle via ubiquitin-mediated proteolysis and their accumulation upon negative growth conditions is mostly achieved transcriptionally (see Sect. 2.5).

2.4.3.2 **Regulation of G1-S phase cyclins proteolysis by the SCF complex.** In human cells, Cyclin E is degraded by

the ubiquitin/proteasome pathway, which requires phosphorylation at Thr380 in an Len-Thr-Pro-Pro (LTPP) motif in Cyclin E by the associated Cdk2 protein kinase. The LTPP destruction sequence is conserved in Xenopus, mouse, and Drosophila Cyclin E, although the functional significance of this motif has not been demonstrated in these systems. Recently, GSK3β has also been shown to facilitate the efficient phosphorylation of Cyclin E at multiple sites to trigger ubiquitin-mediated degradation. GSK3β is a kinase responsive to the PI3K-Akt pathway (see Sect. 2.5.1.4) and therefore, specific phosphorylation of Cyclin E in response to mitogenic stimuli provides a means for developmental regulation of Cyclin E turnover.

Degradation of Cyclin E is dependent on the SCF ubiquitin ligase, in association with another F-box protein, Ago(Cdc4,Fbw7) (see below). The importance of the SCF in Cyclin E degradation is exemplified by the high levels of Cyclin E present in *Cul*$1^{-/-}$ mutant mice (where the SCF does not form). In addition to this mechanism, free Cyclin E, in a phosphorylation-independent manner is also degraded by a non-SCF mechanism, involving a Cul1 related protein, Cul3.

Degradation of Cdk4-associated Cyclin D1 also depends on phosphorylation at a threonine residue at the C-terminus (Thr268) by GSK3β, although it is not known whether this is SCF dependent. However, free Cyclin D1 is degraded via an ubiquitin-mediated mechanism in a phosphorylation-independent manner. Conversely, Cyclin A, which also has roles in the G2-M phase transition, is targeted for degradation by a different ubiquitin-dependent ligase complex, the APC (anaphase promoting complex), which is active in mitosis.

2.4.3.3 **Cyclin E and Ago/Fbw7.** Genetic screens in Drosophila designed to isolate genes that confer proliferative advantage identified *ago* (*hCDC4* in humans and *Fbw7* in the mouse) as the F-box protein that targets Cyclin E for degradation. Loss of *ago* results in excessive cell proliferation and delayed exit from the cell cycle. *ago* mutant cells exhibit elevated levels of Cyclin E protein without affecting its transcription. Ago protein binds to and ubiquitinates phosphorylated Cyclin E and thereby targets it for ubiquitin-mediated degradation.

Fbw7 (hCDC4, Ago)-deficient mice have now been generated that provide parallels with Drosophila *ago* mutants. Although these studies confirmed the role of Fbw7 in Cyclin E regulation, they have also demonstrated that Fbw7 targets a number of other important developmental proteins for degradation. Fbw7-null animals die at E10.5 gestation displaying defects in somitogenesis, heart chamber formation, hematopoiesis, and vascularization in both yolk sac and the embryo proper. These were associated with increased expression of Notch intracellular domains (ICD) and overexpression of Notch targets in the embryo, consistent with what has been observed in Drosophila (see Sect. 2.5.1.7). Importantly, the vascular defects phenocopy that of mice with loss of Notch1 and Notch4, or overexpression of Notch4, further suggesting a role for Fbw7 in control of Notch pathway in mouse development. As would be expected from previous studies, Cyclin E was found to be stabilized in both placenta and embryo and its high expression in *Fbw7*$^{-/-}$ trophoblast giant cells is thought to result in the observed increased DNA synthesis in these trophoblast cells. Of note, *Cul1*$^{-/-}$ mice also show Cyclin E stabilization and increased DNA synthesis

of trophoblast giant cells. These studies suggest the SCF^{Fbw7} complex plays an important role in regulating endocycles in extraembryonic tissue through regulation of Cyclin E levels.

2.4.3.4 **Myc, another G1-S targets of Ago/Fbw7.** Studies in Drosophila have also identified Myc (dMyc, a homolog of c-Myc, a transcription factor involved in regulating of cell growth and proliferation, see Sect. 2.5.1.3) as a new regulatory target for Ago/Fbw7. Overgrowth of *ago* clones in Drosophila suggested that targets other than Cyclin E exist to regulate cell growth. Mass spectrometric analysis and yeast-2-hybrid studies identified d-Myc as a binding partner for Ago. dMyc protein is elevated in *ago* mutant clones. Ago physically binds to dMyc, and halving the dosage of *ago* can rescue the body size and fertility defects of a hypomorphic *dmyc* mutant, although these effects were through increases in cell numbers rather than cell size. Parallel experiments in mammalian cells, revealed that Fbw7 was also required for c-Myc degradation. Consistent with the effect of Fbw7 on c-Myc stability, knockdown of Fbw7 increases cell size, as expected when c-Myc levels are elevated. Similar to Cyclin E, the c-Myc phosphorylation site that conforms to the Cdc4 phosphobinding motif (Thr28), is also phosphorylated by GSK3β and this phosphorylation is required for c-Myc ubiquitination by Fbw7-SCF and subsequent degradation. Interestingly, Thr28 is the most common site of c-Myc mutation in lymphoma. A model has been proposed where Skp2, the other F-box protein known to target c-Myc, regulates basal turnover of c-Myc, while Fbw7 regulates signal-induced degradation of c-Myc. Again, differential phosphorylation provides another strategy for the tight developmental regulation of c-Myc levels. The original studies describing the human homolog of Ago(Fbw7), revealed its mutation in a number of tumors. Since Ago(Fbw7) regulates multiple pathways, such as Myc, Cyclin E, Notch (Sect. 2.5.1.7), and also Jun, its mutation is likely to result in severe disruption to signaling and cell proliferation control and therefore is consistent with its importance in human cancer. Contrary to this notion, however, Fbw7 heterozygous mice do not show increased tumor predisposition. Sensitized backgrounds and/or use of conditional alleles of mouse Fbw7 may clarify its role in tumorigenesis.

2.4.3.5 **Cop9 signalosome in Cyclin E regulation.** Recent studies in the mouse and Drosophila have identified an important role for the COP9 signalosome (CSN) in the regulation of Cyclin E degradation. CSN consists of eight highly conserved proteins, and is important for the modification and activation of Cul1. Cul1 is modified by the conjugation of an ubiquitin-like protein, Nedd8, onto a specific Lysine residue of Cul1 by UBC12. Removal of Nedd8 (deneddylation), by CSN decreases the association of the E2 with Cul1. However, genetic studies in the mouse have shown that CSN is a positive regulator of Cullin-ubiquitin ligases (SCFs), and thus the dynamic cycling of Nedd8 from Cul1 appears to be important for SCF activity. In the mouse, mutation of the CSN components, *Csn2* or *Csn3,* result in destabilization of the CSN and early embryonic lethality. $Csn2^{-/-}$ blastocysts show severe proliferation defects. Consistent with the proposed role for the CSN in Cul1 regulation, $Csn2^{-/-}$ proliferation defects are associated with abnormal Cul1 deneddylation, resulting in stabilization of Cyclin E,

similar to the phenotype observed in *Cul1* mutant mouse tissue. In parallel studies in Drosophila, Csn4 and Csn5 were shown to be required for oogenesis. In particular, *csn5* and *csn4* mutants showed defects in deneddylation of Cul1 and accumulation of Cyclin E. As overexpression of Cyclin E in Drosophila phenocopies CSN mutants, and *csn5* and *cyclin E* mutations suppress each other, it is likely that Cyclin E is a major target for the CSN in early oogenesis.

Thus, in summary, we have discussed three tiers of regulation involved in the accumulation and activity of the G-S phase Cyclin/Cdk complexes; (1) phosphorylation of the Cdk, (2) binding of Cdk inhibitors to regulate kinase activity, and (3) proteolysis to regulate availability of the Cyclin or levels of Cdk inhibitors (see Fig. 8). In addition, Cyclins and Cdk inhibitors are regulated transcriptionally and translationally, and all of these regulatory tiers are impacted upon by inputs from extracellular signals as discussed below.

2.5 Regulation of Cyclin and Cdk Inhibitors by Extracellular Signals

2.5.1 Growth-factor Signaling Pathways in G1-S Regulation

Mitogenic signaling pathways trigger cellular growth (increase in cell mass, by increasing protein synthesis) as well as cell cycle progression. The main mitogenic pathways are the insulin receptor (Inr)-PI3 kinase (PI3K) pathway and the EGFR-Ras pathway, which leads to the upregulation of the transcription factor, Myc. However, signaling pathways that have major roles in tissue patterning can also influence cell growth and proliferation. These include the Hh, Wnt(Wg), TGFβ(Dpp), and Notch pathways. These pathways can induce cell growth and cell proliferation, however, in some contexts the TGFβ(Dpp) and Wg pathways can inhibit cell proliferation. Cells are normally dependent upon mitogenic growth factors for survival and proliferation; however, one of the hallmarks of cancer is growth-factor independence, due to mutations resulting in the activation of signaling pathways.

In the absence of mitogenic stimuli, the levels of free $p27^{KIP1}$ levels are high and thus inhibit the activity of Cyclin E/Cdk2 (see Fig. 9). On the induction of mitogenic pathways, such as the EGFR-Ras and Myc pathways, Cyclin D is transcriptionally activated and as cells accumulate Cyclin D, $p27^{KIP1}$ is sequestered in Cyclin D/Cdk4 complexes, thereby facilitating Cyclin E/Cdk2 activation. Via this mechanism known as Cki exchange, Cyclin E/Cdk2 is activated leading to the phosphorylation of $p27^{KIP1}$ and its ubiquitin-mediated degradation via the SCF (Skp1/Cullin/F-box protein) ubiquitin–ligase complex (see Sect. 2.4.3). In this manner, there is a rapid burst of Cyclin E/Cdk2 activity and cells proceed into S phase. By contrast, antiproliferative (antimitogenic) signals push the equilibrium into the reverse direction, leading to inhibition of Cyclin E/Cdk2 and Cyclin D/Cdk4 activity and arrest in G1 (see Fig. 9).

Specific aspects of these major mitogenic and antimitogenic signaling pathways in regulation of the G1-S-phase regulators will now be discussed.

2.5.1.1 **TGFβ pathway.** The transforming growth factor β (TGFβ; Dpp in Drosophila) signals through the heterodimeric transmembrane receptors, Transforming Growth Factor Receptor (TGFR) type I (Thickvein or Saxophone in Drosophila) and type II (Punt in Drosophila) (see Fig. 10). This results in the phosphorylation of receptor-associated

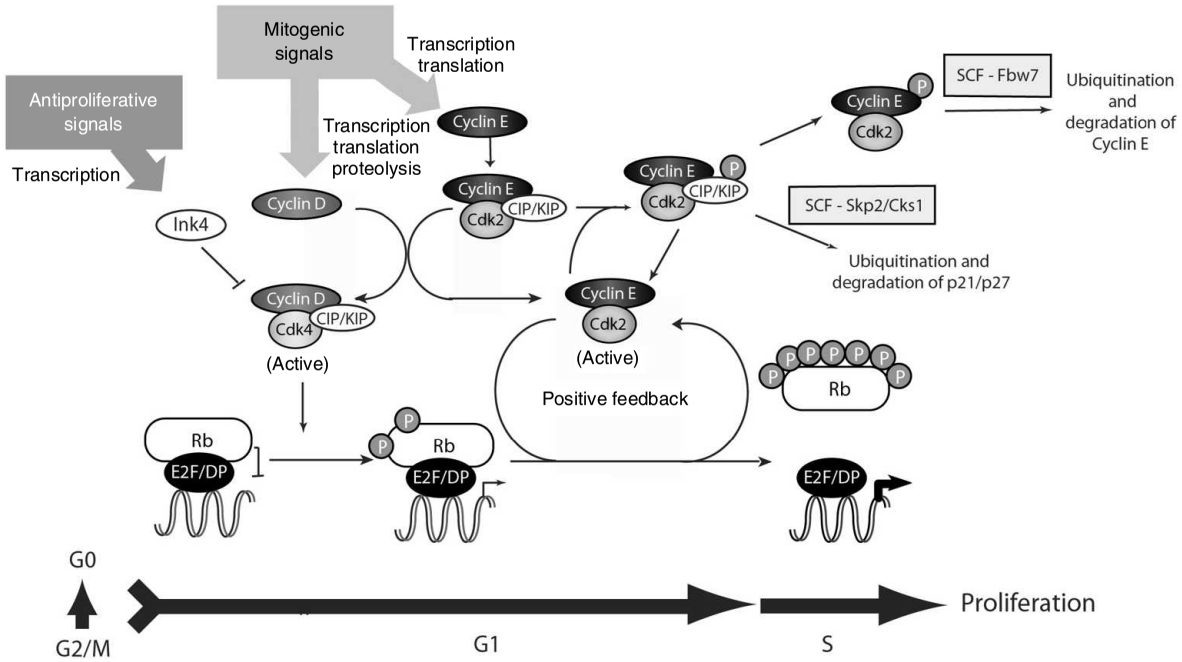

Fig. 8 Summary of G1-S phase progression. Activation of Cyclin D/Cdk4 and Cyclin E/Cdk2 leads to the phosphorylation of Rb and the alleviation of Rb inhibition. Free E2F/DP activates the transcription of genes required for progression into S phase. One of the targets of E2F/DP is *cyclin E*, creating a positive feedback loop, allowing the accumulation of active Cyclin E/Cdk2 kinase at the G1 to S-phase transition. The activity of the Cyclin/Cdk complexes is regulated by the $p16^{INK4A}$ and $p21^{CIP1}$ ($p27^{KIP1}$) family of proteins. $p16^{INK4A}$ binds Cdk4 and prevents binding of Cyclin D, while both $p21^{CIP1}$ and $p27^{KIP1}$ can inhibit Cyclin E/Cdk2 kinase activity, but can act as positive regulators of Cyclin D/Cdk4 assembly. $p27^{KIP1}$ is phosphorylated by Cyclin E/Cdk2, making it a target for the SCF-Skp2/Cks1 ubiquitin–ligase complex and subsequent ubiquitin-dependent degradation by the 26S proteosome complex. Later in S phase, Cyclin E is phosphorylated by the associated Cdk2 protein kinase and by GSK3β, targeting it for ubiquitination by the SCF-Fbw7 ubiquitin ligase followed by ubiquitin-dependent degradation.

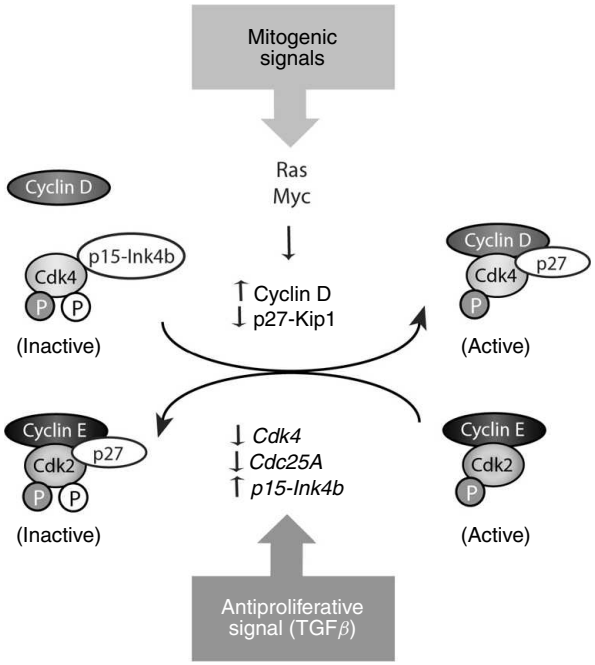

Fig. 9 Cki exchange. During G1, Cyclin/Cdks are in equilibrium between active and inactive states. When the Cdk inhibitor $p27^{KIP1}$ is associated with Cyclin D/Cdk4, it acts to stabilize rather than inhibit this complex. As a consequence, Cyclin E/Cdk2 is freed from inhibition by $p27^{KIP1}$, allowing kinase activity. Mitogenic signaling via Ras and Myc, allows upregulation of *cyclin D* and repression of $p27^{KIP1}$ transcription, further promoting the activation of Cyclin E/Cdk2 allowing progression into S phase. Antiproliferative signals (such as TGFβ) lead to the transcriptional repression of *cdk4*, and *cdc25A*. Since Cdc25A is required to dephosphorylate Cdk2 and Cdk4 (on Tyr15 and 17, respectively) for kinase activation, downregulation of *cdc25A* pushes the equilibrium toward the inactive state. TGFβ also induces expression of $p15^{INK4B}$, which binds specifically to Cdk4 preventing Cyclin D and $p27^{KIP1}$ from binding and inactivating the kinase. Free $p27^{KIP1}$ can then bind to Cyclin E/Cdk2 and inhibit its activity.

Smad transcription factors R-Smads (Smad1, 2, 3, 5, and 8; Mad in Drosophila) enabling their interaction with the Co-Smad (Smad4; Medea in Drosophila). These complexes then translocate to the nucleus and transactivate target genes. Another class of Smads, inhibitory Smads (Smad6 and 7; Dad in Drosophila) antagonize the effect of R-Smads and block TGFβ signaling.

In mammalian epithelial cells, TGFβ negatively regulates cell growth and proliferation. TGFβ induces G1 arrest in epithelial cells via inhibition of Cyclin D/Cdk4(6) and Cyclin E/Cdk2 activity. In the absence of TGFβ signaling, as cells

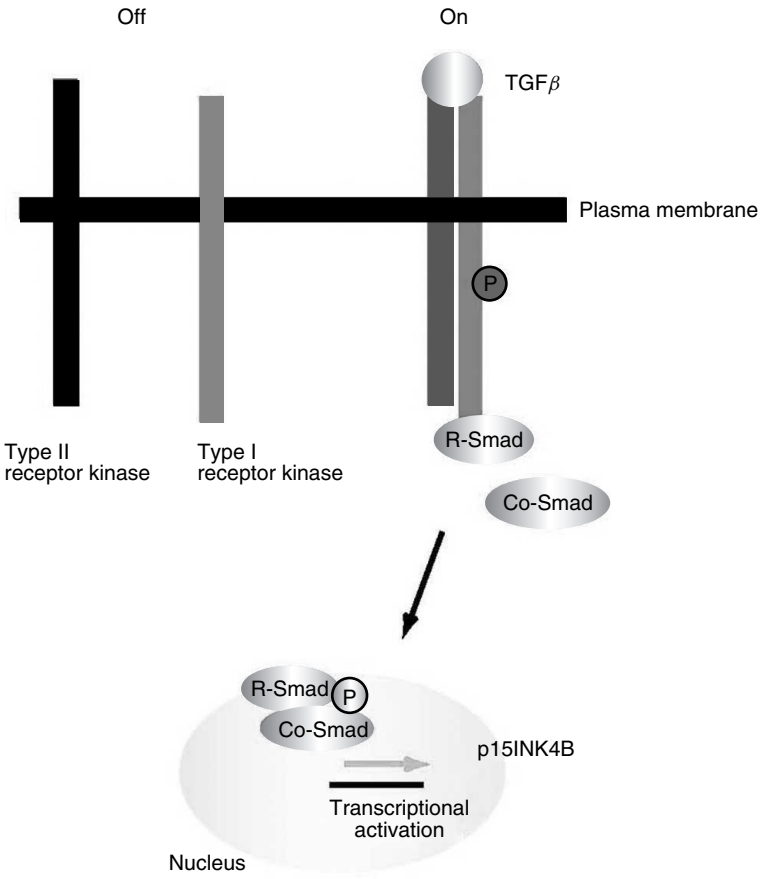

Fig. 10 TGFβ signaling pathway. TGFβ signals though the type I and type II heterodimeric receptor serine–threonine protein kinases. This leads to the activation of the receptor-associated Smad transcription factor (R-Smad) that then binds to another class of Smads (Co-Smad) and enters into the nucleus where it promotes transcription of target genes. The p15^{INK4B} gene is a well characterized downstream target of Smad and TGFβ signaling (see text for details).

progress through the G1-S transition, D-type Cyclins accumulate and Cyclin D/Cdk4(6) sequesters p21^{CIP1}(p27^{KIP1}) away from Cyclin E/Cdk2, thereby allowing its activation. TGFβ signaling induces expression of p15^{INK4B}, a member of the Cdk4(6) class of inhibitors. p15^{INK4B} binds to Cdk4(6), leading to the dissociation of Cyclin D and the release of p27^{KIP1} from this complex. The "free" p27^{KIP1} then acts, via Cki exchange, to bind to and inhibit Cyclin E/Cdk2 activity (see Fig. 9). TGFβ therefore leads to G1 arrest by inhibiting both Cyclin D and Cyclin E-associated kinase activity. However, this is not the only mechanism by which TGFβ induces cells to arrest in G1, as cells derived from p27^{KIP1} knockout mice are

still sensitive to TGFβ. TGFβ also results in downregulation of *cdc25A* transcription, thereby reducing levels of active Cyclin E/Cdk2 and Cyclin D/Cdk4 complexes. In addition, TGFβ leads to downregulation of *cdk4* transcription, which serves to free more $p27^{KIP1}$ from the Cyclin D complexes, allowing exchange to Cyclin E/Cdk2. TGFβ also downregulates *c-myc* expression, which is not only a regulator of cell growth but also of *cyclin D1* transcription, thereby serving to further promote exchange of $p27^{KIP1}$ to Cyclin E/Cdk2. Finally, Smads have also been shown to cooperate with a member of the Forkhead class of transcription factors, FoxO, to upregulate $p21^{CIP1}$ transcription. Thus, TGFβ acts via $p27^{KIP1}$ dependent and independent mechanisms to mediated G1 arrest.

The Drosophila TGFβ superfamily member Decapentaplegic (Dpp) acts to stimulate cell growth and proliferation in some contexts, but to inhibit cell proliferation in other contexts. In early development, and in third instar larval wing imaginal discs, loss of *dpp* expression results in reduced tissue size. However, in the third instar larval eye imaginal disc, *dpp* mutant clones exhibit ectopic cell proliferation, while increasing Dpp signaling leads to G1 arrest. Recent studies have shown that the mechanism for this cell cycle inhibition by Dpp is likely to involve both the Drosophila Retinoblastoma-E2F pathway and the Drosophila $p21^{CIP1}$($p27^{KIP1}$) homolog, Dap.

2.5.1.2 **EGFR–Ras pathway.** The small GTPase, Ras, is a key signaling protein that is regulated by numerous receptor tyrosine kinases. One major modulator is the epidermal growth-factor receptor (EGFR), which is a transmembrane protein that interacts with different ligands, to activate Ras and the MAP Kinase (MAPK or ERK) pathway (see Fig. 11). The Ras GTPase is active in its Guanosine 5'-triphosphate (GTP)-bound state, but inactive when bound to Guanosine 5'-diphosphate (GDP), and when active, triggers the MAPK pathway. Oncogenic (activated) forms of Ras, are due to mutations that lock Ras in the GTP-bound state (e.g. Ras Valine-12 mutation) and contribute to ~25% of all cancers. The MAPK pathway, involves the serial activation of Raf (MAPKKK), MAPKK (MEK), and MAPK (ERK) kinase cascade leading to different outcomes depending on the cell context. Ras can also upregulate other signaling pathways, such as the PI3K pathway (see below) and lead to the activation of another small GTPase, Ral. In mammalian cells, the importance of Ras in cell proliferation is exemplified by the G1 arrest observed when neutralizing antibodies to Ras, or dominant-negative versions of Ras (blocked in the GDP-bound state) are injected into growth-factor stimulated cells, and the prevalence of activated Ras mutations in cancer. In Drosophila, EGFR–Ras signaling also regulates cell cycle progression, as well as cell growth, survival, differentiation, and patterning during development.

The Ras–MAPK cascade acts via phosphorylation of numerous effectors, including transcription factors of the Ets family, and Jun and Fos(Fra), which dimerize to generate the AP1 transcription factor. Likewise, in Drosophila, Ras signaling activates the Ets-family transcription factors, Pointed and Yan, and also the Jun/Fos transcription factor. In mammalian cells, an important function of the Ras–MAPK pathway is to phosphorylate and stabilize the c-Myc transcription factor, which plays an important role in cell growth and proliferation (see Sect. 2.5.1.3). In Drosophila,

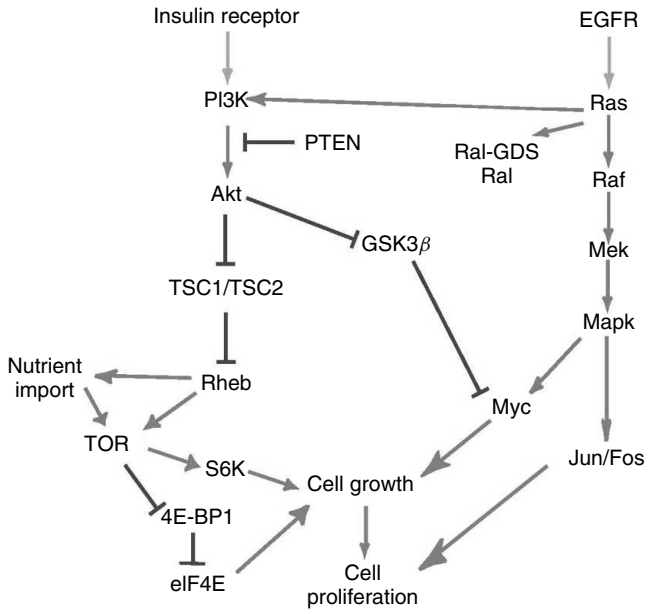

Fig. 11 Mitogenic signaling pathways – Ras, Myc, and Insulin-PI3K EGFR-Ras signaling activates the MAPK cascade leading to upregulation of transcription factors, such as Jun/Fos (AP1), and acts to phosphorylate and stabilize Myc. Ras and Myc regulate cell growth by increasing the transcription of translation initiation factors and ribosomal components, and promote the cell cycle by positively regulating Cyclin E levels or Cyclin E/Cdk2 activity. Signaling through the insulin receptor pathway occurs via PI3K and AKT, which phosphorylates and inactivates the Tsc1/Tsc2 complex, leading to activation of Tor and S6 kinase. Activation of S6 kinase results in increased cellular growth and promotes the G1-S phase transition. AKT activation also leads to phosphorylation of GSK3β, which acts to antagonize Myc and core cell cycle components, such as Cyclin E by phosphorylating them and targeting them for ubiquitin-mediated degradation. See text for further details.

activation of Ras also leads to upregulation of the Myc transcription factor, by an unknown mechanism.

Ras-mediated G1-S progression requires the inactivation of Rb, which depends upon the upregulation of *cyclin D1* transcription via the activation of Jun and Fos(Fra) transcription factors, which bind to the AP1 site on the Cyclin D1 promoter. Ras also acts to promote translation of Cyclin D1, to increase Cyclin D1 protein stability via activation of the PI3K pathway (and inhibition of GSK3β-mediated phosphorylation, which triggers ubiquitin-dependent degradation of Cyclin D; see Sect. 2.4.3 and the following). Activation of Ras also leads to decreased $p27^{KIP1}$ transcription through repression of the Forkhead transcription factors, decreased $p27^{KIP1}$ protein synthesis, and decreased $p27^{KIP1}$ protein stability through both Cdk2-dependent and independent

mechanisms. Finally, Ras signaling, via the MAPK pathway, directly affects cell growth by leading to the phosphorylation of the Mnk protein kinase that phosphorylates the eukaryotic initiation factor eIF4E and enhances its activity. Thus, Ras signals through many pathways to promote cell cycle progression.

Conversely, in some contexts high levels of Ras signaling can trigger upregulation of $p21^{CIP1}$, $p15^{INK4B}$ and $p16^{INK4A}$ and downregulation of *cdk4*, leading to cell cycle arrest. Upregulation of other pathways, such as the Rho GTPase pathway, which blocks $p21^{CIP1}$ expression, is required to overcome the G1 arrest caused by high levels of activated Ras signaling. Recent studies have also shown that in cells with high levels of Ras signaling, the transcription factor, NF-κB, is responsible for inhibiting *cdk4* transcription, and if NF-κB activity is blocked, then activated Ras-expressing cells show unrestrained cell proliferation.

2.5.1.3 **Myc.** c-Myc is a basic-helix-loop-helix-zipper (bHLHZ) transcription factor that dimerizes with a related protein, Max, and is upregulated in response to many growth-factor signaling pathways. c-Myc/Max complexes regulate genes involved in cell growth and metabolism, such as translation initiation factors and ribosomal mRNA and proteins. Myc also promotes the G1 to S phase progression in both mammalian cells and Drosophila. Drosophila *dmyc* mutations produce small adults, suggesting a role in cell and tissue growth. Indeed, Drosophila wing disc cells that express higher levels of dMyc compared with surrounding cells ''outgrow'' the neighboring cells by exhibiting faster rates of cell growth and cell proliferation, as well as inducing apoptosis in the neighboring cells. dMyc increases transcription of *Cyclin E* and the activity of Cyclin D/Cdk4, as well as increasing the levels of Cyclin E posttranscriptionally. In mammalian cells, c-Myc has also been shown to induce the transcription of D-type Cyclins, and in association with a zinc-finger transcription factor, Miz1, acts to repress transcription of the $p21^{CIP1}$ and $p15^{INK4B}$ genes.

c-Myc is normally rapidly turned over via ubiquitination and proteasomal degradation (see Sect. 2.4.3.4). The EGFR-Ras-MAPK signaling pathway (as seen earlier) regulates the level of c-Myc via phosphorylation of the Ser62 residue, resulting in c-Myc stabilization (Fig. 11). In Drosophila, the Ras pathway also leads to upregulation of dMyc, although the mechanism has not yet been elucidated. While phosphorylation of c-Myc at Ser62 stabilizes it, this event allows the subsequent phosphorylation at Thr58 by GSK3β, which leads to ubiquitin-mediated degradation of c-Myc (see Sect. 2.5.1.3). This mechanism provides tight control of c-Myc levels, which is important for strict regulation of G1-S phase progression. The importance of controlling Myc is highlighted by the prevalence of Myc overexpression in cancers.

2.5.1.4 **Insulin receptor-PI3 kinase pathway.** The insulin receptor (Inr) pathway (see Fig. 11) acts through the phospholipid kinase PI3-Kinase (PI3K), the protein kinase AKT (PKB), the protein kinase Tor, and S6 kinase (S6K), which together lead to increased cellular growth by induction of the protein translation machinery. The protein kinase Tor, also responds to nutrient levels to induce ribosome biogenesis. In mammalian cells, activation of PI3K stimulates S phase via increased Cyclin D/Cdk4 and Cyclin E/Cdk2 activity.

The PI3K pathway acts through AKT to phosphorylate and inactivate GSK3β, which normally acts to inhibit G1-S progression via phosphorylation of Cyclin D, E, and c-Myc, thereby promoting their ubiquitin-mediated degradation (see Sect. 2.4.3). AKT also downregulates Cdk inhibitors by several mechanisms: AKT phosphorylates $p27^{KIP1}$ and $p21^{CIP1}$, sequestering them to the cytoplasm; leads to upregulation of Skp2, the F-box component of the SCF, which targets phospho-$p27^{KIP1}$ and $p21^{CIP1}$ for ubiquitin-mediated degradation; and phosphophorylates and inactivates Forkhead transcription factors thereby preventing the transcription of $p27^{KIP1}$ and $p21^{CIP1}$. AKT also facilitates the assembly of CyclinD/Cdk4/$p27^{KIP1}$ complexes, thereby allowing activation of Cyclin E/Cdk2 via Cki exchange.

In Drosophila, the Tubulous Sclerosis Complex (TSC1/TSC2) complex, a downstream component of the InR pathway (see Fig. 11), acts to repress S6K activity and decrease Cyclin E levels. In the absence of Inr activity, the TSC1/TSC2 complex, acts to repress the Rheb GTPase, which is required to activate TOR and S6K. Activation of Inr inhibits TSC1/TSC2, therefore relieving inhibition of Rheb and allowing S6K and Tor activation and subsequent phosphorylation of the ribosomal protein S6. S6 phosphorylation stimulates translation of a specific class of mRNAs, the so-called TOP (terminal oligopyrimidine tract in the 5′UTR) mRNAs that encode ribosomal proteins and elongation factors. Tor also phosphorylates and inactivates 4E-BP1, an inhibitor of the eIF4E translational initiation factor, thereby generally increasing translation. Mutational analysis of *tsc1/tsc2* in Drosophila shows that loss of this complex leads to increased S phases and Cyclin E levels.

2.5.1.5 **Hedgehog pathway.** The Hedgehog (Hh) signal is transmitted through two transmembrane proteins, Patched (Ptc) that accumulates in intracellular vesicles (endosomes) and Smoothened (Smo) that predominantly localizes to the plasma membrane (see Fig. 12). The zinc-finger transcription factor Gli (or Ci in Drosophila) acts in an Hh-dependent manner, to repress or activate target genes. In the absence of Hh signaling, Smo is inhibited indirectly by Ptc and directly by the kinesin-related protein Costal2 (Cos2), which causes internalization of Smo into endosomes, a process dependent upon actin, microtubules, and endocytosis proteins. Internalization of Smo, leads to the degradation of Ci (Gli) into its repressor form (Ci^{75} in Drosophila), which requires PKA phosphorylation and Nedd8 modification of the Cul1-based SCF^{Slimb} complex. At the same time, full-length Gli (Ci^{155} in Drosophila) is tethered to microtubules by Cos2, Fused and Suppressor of Fused (Su(Fu)), and further regulated by constitutive export from the nucleus. In Drosophila, the Ci^{75} repressor form localizes to the nucleus, where it inhibits transcription of targets such as *hh* and the TGFβ family member, *dpp*. In the presence of the Hh signal, Ptc inhibition of Smo is overcome, resulting in Smo activation and translocation from internal membranes to the cell surface, in a Cos2-dependent manner. This leads to the stabilization of full-length Ci^{155}, which translocates to the nucleus and activates targets, such as *hh*, *ptc*, *dpp* in Drosophila.

In Drosophila, Hh signaling was first implicated in cell proliferation when *ptc* mutants were identified in a genetic screen for regulators of Retinoblastoma (RBF1). Furthermore, *smo* mutants prevent cells in the posterior region of the third instar larval eye imaginal disc from entering

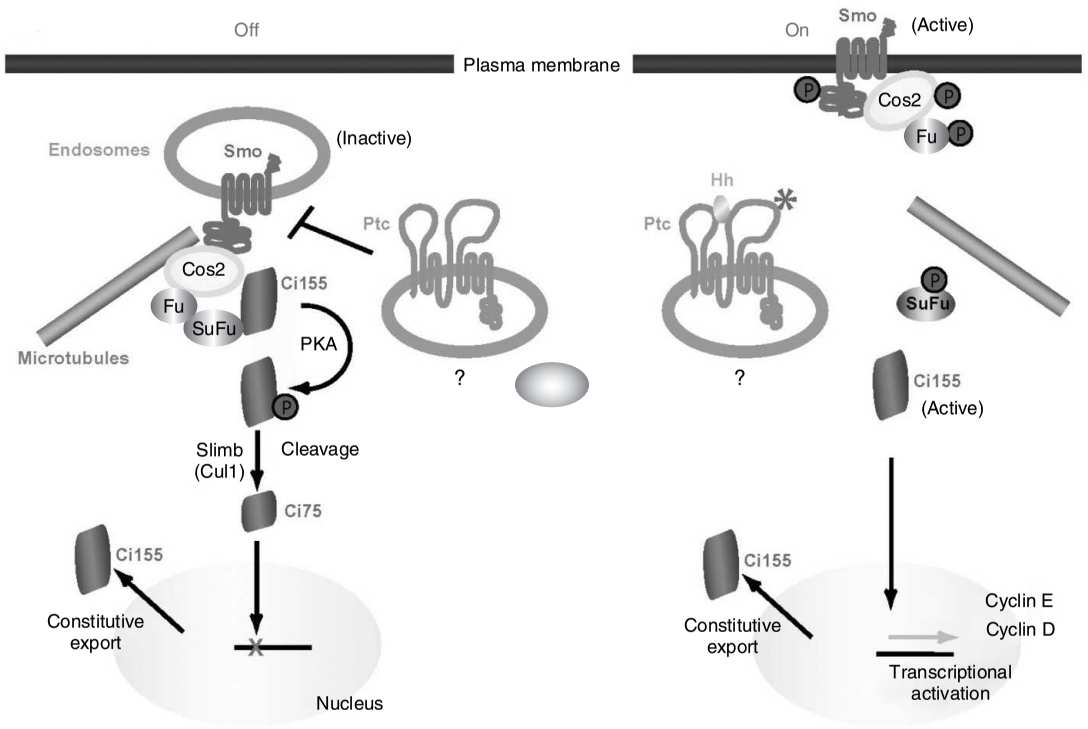

Fig. 12 Hh signaling pathway. In the absence of the Hedgehog signal, the transmembrane protein Patched localizes to endosomes and inhibits the activity of Smoothened via an unknown mechanism. Inactive Smoothened localizes to endosomes and is anchored to the cytoplasm via interaction with the Cos2/Fu/Su(Fu)/Ci complex which binds to microtubules. Formation of the Cos2/Fu/Su(Fu)/Ci complex allows the interaction with PKA and the subsequent phosphorylation of Ci. Phosphorylated Ci undergoes Slimb/Cul1 mediated degradation that yields a transcriptional repressor form of Ci. In the presence of the Hedgehog signal, Patched binds Hedgehog and relieves its repression upon Smoothened. Signaling by Hedgehog also leads to phosphorylation of Fu, Cos-2 and Su(Fu) via an unknown mechanism. The Cos2/Fu/Su(Fu)/Ci complex dissociates, and activated Smoothened moves to the plasma membrane in a Cos2-dependent manner. Free Ci is able to enter the nucleus and activate the transcription of its targets. Both *cyclin E* and *cyclin D* have been reported to be downstream targets of Ci and the Hedgehog pathway (see text for details).

S phase. Conversely, overexpression of Ci^{155}, results in ectopic S-phase entry in cells normally in G1 in the third instar larval eye and wing imaginal discs and the brain lobes. Moreover, Ci^{155}-induced S-phase entry is Rb-independent, since ectopic S phases are still observed in the presence of a nonphosphorylatable and constitutively active version of Rb, $RBF1^{280}$ (see Sect. 2.3.5). However, upregulation of Ci in the third instar larval eye imaginal disc, results in ectopic Cyclin E expression, which is due to the direct binding of Ci^{155} to the *cyclin E* promoter and induction of *cyclin E* transcription. This is consistent with the observation that progression into S phase in the posterior region of the eye disc is an dE2F1-independent process.

The Hh pathway also regulates Cyclin D expression in the Drosophila eye imaginal disc. Normally, Cyclin D is expressed in the posterior region of the Drosophila eye disc, with the highest level of expression coinciding with Ci expression in cells undergoing the G1-S phase transition. Consistent with Hh signaling normally being required for Cyclin D expression, reduced levels of Cyclin D are observed in *smo* mutant cells, and overexpression of Ci induces high levels of *cyclin D* transcript in the third instar larval eye and wing imaginal discs. Furthermore, overexpression of Patched reduces cell growth and cell proliferation, which can be overcome by coexpression of Cyclin D/Cdk4, indicating that Cyclin D is an important downstream target of Hh. Thus Hh signaling upregulates the two cyclins required for cell growth and cell proliferation in the Drosophila eye disc. It remains to be determined how general this mechanism is in Drosophila cell cycles and whether this is also the case in mammals Indeed, recent studies have shown that Hh signaling, like Dpp may be important in the developmental F1 arrest during Drosophila eye development.

2.5.1.6 **Wnt (Wingless) pathway.** Wnt or Wingless are extracellular morphogens that act through Frizzled receptors, to mediate signaling through several different pathways. In the canonical pathway (which we consider here), Wnt signaling leads to the transcriptional activation by β-catenin, an important transcriptional regulator of cell cycle genes (see Fig. 13). In the absence of Wnt signaling, β-catenin is localized to the cytoplasm in a complex with the two scaffolding proteins, adenomatous polyposis coli tumor suppressor protein (Apc) and Axin, which mediate phosphorylation of β-catenin by GSK3β, and subsequent degradation. Apc can also shuttle into the nucleus, and when overexpressed, acts in the nucleus to block G1-S progression. In the presence of Wnt, activation of the canonical Wnt signaling pathway results in stabilized, nuclear-localized β-catenin, which interacts with the HMG-box transcription factor (TCF), to activate transcription of cell cycle target genes including *c-myc* and *cyclin D1*.

In Drosophila wing development, Wingless (Wg) signaling is required for cell survival, as cells deprived of Wg activity die at a high frequency. However, inhibition of cell death in cells deprived of Wg activity, results in increased proliferation correlating with increased dE2F1 activity. Conversely, activation of the Wg pathway leads to reduced cell proliferation correlating with reduced dE2F1 activity. In contrast to observation in mammalian cells (as seen earlier), upregulation of Wg signaling in Drosophila inhibits *dmyc* expression in the third instar larval presumptive wing margin cell (referred to as

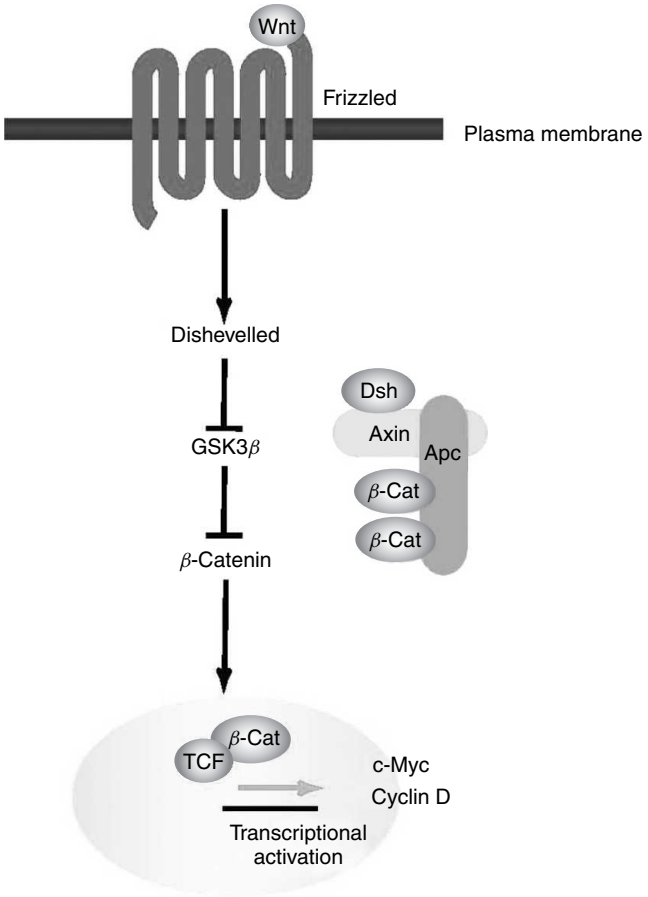

Fig. 13 Canonical Wnt (Wingless) signaling pathway. Wnt, or Wingless (Wg) in Drosophila, signals through the Frizzled transmembrane receptor and the PDZ-containing adaptor protein, Disheveled, to lead to the inactivation of the serine/threonine kinase GSK3β. In the absence of Wnt in mammalian cells, β-catenin is normally bound by a complex containing adenomatous polyposis coli protein (Apc), Axin and GSK3β, which phosphorylates and targets β-catenin for degradation. In the presence of the Wnt signal, Disheveled binds to Axin, excludes GSK3β and allows β-catenin to accumulate. Stable β-catenin translocates to the nucleus where it forms a complex with the HMG-box transcription factor, TCF (LEF1), and transactivates expression of target genes. Both *c-myc* and *cyclin D* have been reported to be downstream transcriptional targets of the Wnt pathway (see text for details).

the zone of nonproliferating cells, ZNC). In these cells, Wg-mediated downregulation of *dmyc* leads to an RBF1-mediated G1 arrest. However, in other tissues, such as the eye imaginal disc, upregulation of Wg signalling promotes cell proliferation.

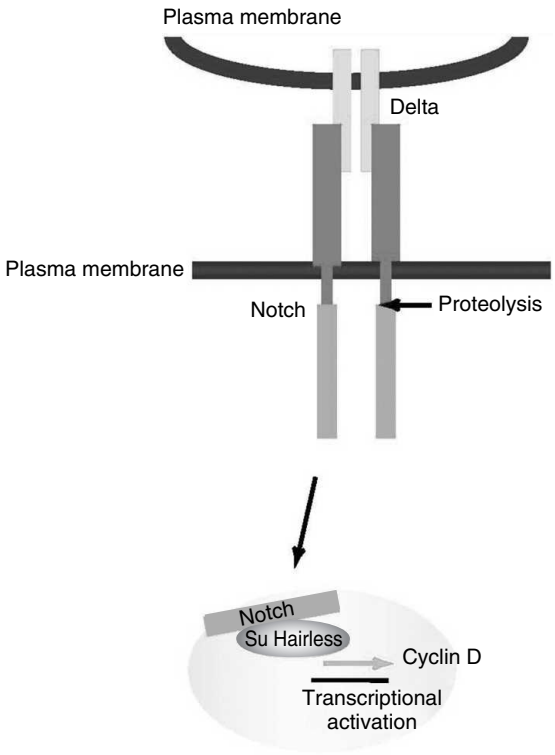

Fig. 14 Notch signaling pathway. In the Notch signaling pathway, the sending cell expresses Delta or Serrate, which are ligands for the Notch receptor at the receiving cell. Activation of Notch leads to its cleavage and its localization to the nucleus, where it associates with the coactivator Su(Hairless) to regulate transcription of its targets. *Cyclin D* has been reported to be a downstream target of the Notch pathway (see text for details).

2.5.1.7 **Notch pathway.** Notch is a family of large transmembrane proteins that mediate multiple cellular processes, including proliferation, differentiation, and apoptosis, by interacting with the transmembrane protein Delta in the adjacent cell. Notch signaling leads to cleavage of Notch and release of the Notch intracellular domain, which can enter the nucleus and bind to the transcription factor, Su(H), activating transcription of target genes (Fig. 14). In mammalian cells, Notch signaling leads to the induction of *cyclin D1* transcription and the activation of the Cdk2 protein kinase, promoting entry into S phase. In Drosophila eye development, Notch regulates neural cell differentiation, but also promotes cell proliferation. Recently, Notch signaling has been shown to play an important role in driving the developmental synchronized S phases during Drosophila development. While in other studies ectopic Notch signaling has been shown to promote cell proliferation in the developing eye by upregulation of the Jak kinase-Stat transcription factor signaling pathway and the Eyg transcription factor. Interestingly, Cyclin D/Cdk4 appears to act downstream of Jak, and plays a role in the stability of the Stat transcription factor. Furthermore, in Drosophila oogenesis, Notch signaling has been shown to have a role in the downregulation of the CIP(KIP) homolog, Dacapo, which is required to alter the cell cycle mode (see Sect. 2.7.2.2). However, in other contexts such as the developing wing Notch signaling can act to inhibit cell proliferation.

In conclusion, extracellular signaling via growth-factor receptors play a major role in regulating the G1-S phase transition through affects on transcription, translation, and proteolysis of cyclins, Cdks, and Cdk regulators. There are, however, additional mechanisms by which extracellular factors can regulate G1-S phase progression, which is by the interaction of cells with their neighbors and via their tissue context (see below).

2.5.2 Regulation of G1-S Phase Progression by Anchorage, Contact Inhibition, and Tissue Architecture

From the earliest days of growing cells in tissue culture, it was noted that cell proliferation was influenced by two events. First, cells depended upon attachment to the culture dish in order to enter into the cell cycle, a phenomena known as *anchorage dependence*. Second, it was observed that when cells grew to confluency, cells arrested in G1 phase, a phenomenon known as *contact inhibition*. These controls were known to be important for restraining cell proliferation, since loss of anchorage dependence and contact inhibition are hallmarks of cancer. It is now known that both of these events are due to communication between a cell and the neighboring cell or between the cell and the extracellular matrix (ECM, a complex ordered network of proteins, such as laminin and fibronectin).

Anchorage-dependent proliferation requires signaling through integrins after they have bound to their substrates in the ECM. Integrin-mediated adhesion via upregulation of the tyrosine kinases, Focal adhesion kinase (FAK) and Src, can lead to the upregulation of many signaling pathways, such as the Rac GTPase, PI3K (Sect. 2.5.1.4), Ras–MAPK (Sect. 2.5.1.2) and the Jun kinase pathways. Activation of these pathways, can lead to the activation of the Jun/Fos (AP1) and β-catenin transcription factors that are important for *cyclin D* transcription (see Sects. 2.5.1.2 and 2.5.1.5). Moreover, activation of the PI3K pathway, via AKT, leads to upregulation of Cyclin D translation and protein accumulation, and downregulation of Cdk inhibitors, and thereby leads to activation of Cyclin E/Cdk2 (see Sect. 2.4.2). Anchorage-dependent proliferation also requires the transcription of the *cyclin A* gene, via p107/E2F4 regulation, at the onset of S phase. Thus, by signaling through multiple pathways after contact with ECM components, integrins promote the upregulation of cyclin/Cdk activity and entry into S phase. By contrast, in some contexts, contact of specific integrins with particular components of the ECM can act to limit cell proliferation; however, the mechanism by which this occurs is not well understood.

Contact inhibition acts primarily through adherens junctions, which are specialized junctional complexes involved in cell–cell connection and signaling. Key proteins at adherens junctions, are the cadherins, such as E-cadherin and N-cadherin, which are large transmembrane proteins that form complexes with the cytoskeletal protein, α-catenin, and with the transcription factor, β-catenin (see Sect. 2.5.1.5). By sequestering β-catenin to the membrane, cadherins, prevent β-catenin from entering the nucleus, thereby preventing transcription of *c-myc* and *cyclin D*. The cadherin complex also regulates other pathways, such as the Rac GTPase, which can inhibit signaling via another GTPase, Rho. Rho activation in mammalian cells has been shown to promote cell cycle progression by leading to downregulation of the cyclin/Cdk inhibitors $p21^{CIP1}$ and $p27^{KIP}$, and upregulation of Cyclin D

and Cyclin E. Within a whole organism, contact inhibition via the adhesion junctions also appears to be important in limiting cell proliferation. In mouse models and in human disease conditions, disruption of the integrity of adherens junctions by mutations in the junctional proteins, α-catenin or E-cadherin, leads to hyperproliferation and tumorigenesis. For example, ablation of E-cadherin and α-catenin in mouse skin leads to hyperproliferation. The epithelial hyperplasia in mice mutant for α-catenin, is associated with ectopic Ras-MAPK signaling. Ectopic activation of signaling pathways, has also been observed in other studies when cellular architecture is disrupted, and was shown to be due to the breakdown of cell polarity, which normally acts to separate ligands and their receptors to exclusive cellular compartments.

Within a whole organism, the architecture of the tissue, the arrangement of individual cells to each other, can also be an important factor in restraining inappropriate cell proliferation. Epithelial cells, in particular, exhibit a highly organized cell shape (cell polarity), which requires the formation of specialized junctional complexes, the Bazooka complex, Crumbs complex, Dlg complex, and the adherens junctions, along their apical–basal axis (Fig. 15). The importance of cell polarity and integrity of junctional complexes to cell proliferation control, is dramatically exemplified by the Drosophila neoplastic tumor suppressor genes, *dlg,* encoding a Membrane Associated Guanylate Kinase (MAGUK) protein, *scrib* (encoding a leucine rich repeat, LRR and PDZ domain protein) and *lgl* (encoding a WD40 domain-containing protein). Dlg and Scrib localize to the septate junctions, and genetically interact with Lgl, which is cytoplasmically and cortically localized. In the absence of any of these proteins, correct polarization of epithelial tissues and neuroblasts is disrupted, the tissue fails to properly differentiate, and cells upregulate Cyclin E and overproliferate to form large invasive tumors. The ability of Scrib, Dlg, and Lgl to regulate cell polarity and proliferation is likely to be conserved in the mouse, since mouse *lgl1* mutant exhibit defects in neural progenitor cell polarity associated with overproliferation. A second Lgl homolog, Lgl2, also exists and exposing redundant functions will require the generation of an Lgl2 knockout and analysis of the double mutant. Four Dlg homologs exist in the mouse, the overlapping functions of which are yet to be explored *in vivo*. However, Scrib is represented by a single gene (*Scrb1*), mouse mutants of which exhibit dramatic developmental defects in neural tube closure, although cell proliferation defects have not yet been reported. Interestingly, however, both Dlg and Scrib proteins contain PDZ domains and are targeted for degradation by the E6 onco-protein of high-risk human papilloma viruses, which appears to be important for E6's ability to promote epithelial hyperplasia.

A central issue raised by studies of *scrib, lgl*, and *dlg* mutants is whether excessive cell proliferation is a consequence of disrupting cell polarity or due to cell polarity-independent functions of these proteins. At this stage, very little is known of the molecular mechanism by which, Lgl, Dlg, or Scrib connect to the cell cycle. Studies in Drosophila suggest that the polarity and proliferation defects of *lgl* mutants can be suppressed by reducing the dosage of atypical protein kinase C (aPKC), a component of the Bazooka apical complex). However, it is not clear whether this reflects a positive cell cycle role for aPKC downstream of Lgl, or an inhibitory

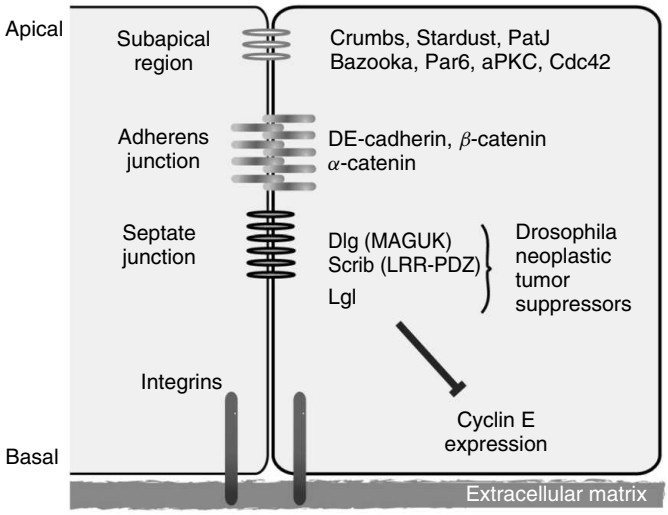

Fig. 15 Cell polarity and G1-S regulation. A polarized epithelial cell exhibits distinct domains of membrane associated-protein complexes along its apical–basal axis. At the apical surface, known as the subapical region, there are two complexes: The Crumbs complex (Crumbs/Stardust/Patj) and the Bazooka complex (Bazooka/Atypical Protein Kinase C (aPKC)/Dpar-6/Cdc42). Below the subapical region lies the adherens junction where, E-cadherin, β-catenin and α-catenin form a complex. Basal to the adherens junction, is the septate junction in Drosophila (or the basal region in mammalian cells), where Dlg and Scribble (Scrib) are located. Lgl can also concentrate at the septate junctions and genetically interacts with Scrib and Dlg. At the basal surface of the cell, the transmembrane Integrin proteins localize and form connections to components of the extracellular matrix. In Drosophila Dlg, Scrib, and Lgl are neoplastic tumor suppressors and mutation in any one of these proteins leads to loss of polarity and uncontrolled cell proliferation. Dlg, Scrib, and Lgl work in a common pathway to regulate cell polarity and inhibit G1-S progression by preventing Cyclin E expression.

role for aPKC on Lgl function. In the *lgl1* mouse knockout, the hyperproliferation of neural cells is correlated with mislocalization of Numb, a protein involved in asymmetric division, and ectopic Notch signaling. Consistent with this, there are strong similarities between the hyperproliferation defects of the *lgl1* knockout and the conditional double knockout of Numb and Numblike. In this context, therefore, it seems likely that defects in the regulation of cell asymmetry are primarily responsible for the inappropriate activation of a signaling pathway promoting ectopic cell proliferation.

Intriguingly, a specific connection between the regulation of Cyclin E and cellular architecture has recently emerged from a genetic screen in Drosophila for dominant suppressors of a *cyclin E* hypomorphic allele. Unexpectedly, within this sensitized background, adhesion and cytoskeleton genes (including *scrib*, *dlg*, and *lgl*) were identified as negative regulators of

cyclin E. This suggests that there are direct links between the polarized cell architecture and the cell cycle machinery *in vivo*. Indeed, analysis of mutants and dissection of domains for Drosophila Dlg and Scrib, suggest that their cell proliferation role is separable from their role in cell polarity, although how these genes regulate Cyclin E levels is not known.

In conclusion, progression into S phase depends upon extracellular inputs, both from diffusible growth factors, and through contact with neighboring cells and the ECM. Moreover, the structure (shape) of a cell is very important in enabling appropriate contacts with adjacent cells and with the ECM, as well as for correct localization of growth-factor receptors to provide strict control of cell proliferation. When these controls fail, inappropriate cell proliferation can ensue, leading to cancer.

2.6 Regulation of G1-S Phase by the DNA-damage and DNA-replication Checkpoint: p53

Another important control of G1-S phase progression occurs in response to DNA damage or DNA-replication errors. These controls are known as the DNA-damage and DNA-replication G1 checkpoints. When DNA is damaged or DNA replication is halted in response to environmental assaults, monitoring proteins sense the damage or impairment and lead to cell cycle arrest until the damage can be repaired or apoptosis (regulated cell death) is triggered to eliminate the damaged cell. This checkpoint control is very important to maintain genomic integrity, and if this mechanism fails the accumulated DNA damage and/or chromosome loss (aneuploidy) is highly conducive to the development of cancer. The tumor suppressor, p53, is a major player in the DNA-damage and DNA-replication checkpoint mechanism, and its importance in this mechanism is highlighted by its mutation in most human cancers.

In G1 or S phase cells, p53 is activated in response to DNA damage and DNA-replication errors by a signaling cascade involving the ATM (ataxia telangiectasia mutated) or ATR (ATM-related) and the Chk2 protein kinases (see Fig. 16). ATM is activated by double-strand DNA breaks due to ionizing radiation, while ATR is activated by DNA base damage due to ultraviolet radiation and by unreplicated DNA. The p53 transcription factor is normally highly unstable due to ubiquitin-mediated degradation, mediated by the Mdm2 ubiquitin ligase. Upon phosphorylation by ATM or ATR and Chk2 protein kinases, p53 is stabilized and is able to transactivate targets involved in cell cycle arrest, DNA repair, and apoptosis. The critical p53 target required for G1 phase arrest is the $p21^{CIP1}$ Cdk inhibitor. By upregulation of $p21^{CIP1}$, the DNA damage or DNA-replication checkpoint pathways lead to inactivation of cyclin-Cdks and arrest in G1 or S phase, until the damage can be repaired. In Drosophila, the p53 pathway is also conserved and acts in response to DNA damage; however, the outcome of this pathway in Drosophila is focused toward upregulation of the apoptotic pathway, and not upregulation of the CIP(KIP) homolog, Dacapo.

An additional layer of regulation on p53 activity is mediated by the $p19^{ARF}$ protein, which is encoded by an alternative reading frame in the $p16^{INK4A}$ locus. In response to high levels of mitogenic signaling and upregulation of the Ras, Myc, and E2F pathways, transcriptional upregulation of both $p16^{INK4A}$ and

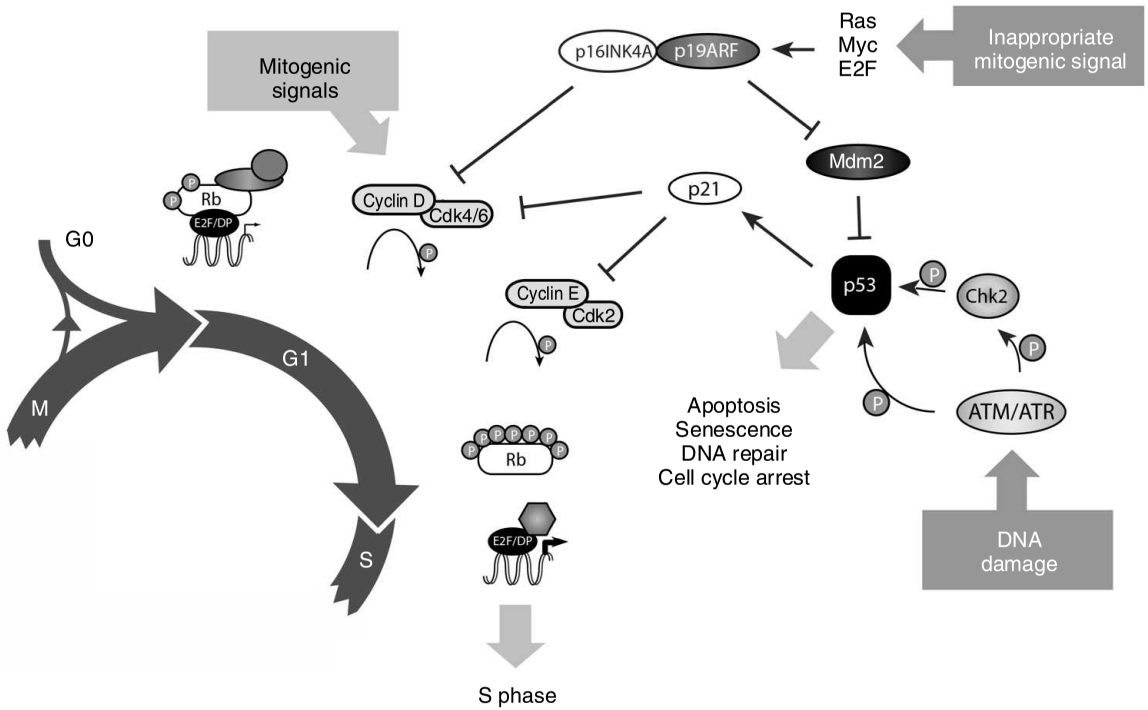

Fig. 16 DNA damage and DNA replication G1-S checkpoint: p53. Upon DNA damage or perturbations to DNA replication, the protein kinases ATM and ATR are induced. Activation of ATM (ATR) leads to phosphorylation and activation of the Chk2 protein kinase and phosphorylation of the tumor suppressor transcription factor, p53. Phosphorylation of p53 stabilizes it, allowing it to activate target genes, such as $p21^{CIP1}$, resulting in inhibition of Cyclin/Cdks and G1-S phase arrest. p53 can also trigger DNA repair, apoptosis and senescence. In addition, inappropriate mitogenic signaling through Ras, Myc, and/or E2F results in transcriptional induction of the *INK4A* locus, that encodes both the Cki $p16^{INK4A}$ and the tumor suppressor $p19^{ARF}$. The INK4A locus therefore controls two pathways necessary for cell cycle arrest, $p16^{INK4A}$ inhibits Cyclin D/Cdk4 assembly and $p19^{ARF}$ downregulates the p53 ubiquitin-ligase Mdm2 resulting in stabilization of p53, transcription of $p21^{CIP1}$ and inhibition of Cyclin E/Cdk2.

$p19^{ARF}$ occurs. While $p16^{INK4A}$ inhibits cyclin/Cdk4 activity, $p19^{ARF}$ acts to stabilize p53 by inhibiting the Mdm2 ubiquitin ligase. The convergence of the $p16^{INK4A}$-Rb and $p19^{ARF}$-p53 pathways at the *INK4A* locus remains an evolutionary puzzle as it provides a doubly effective target for mutation. Indeed, the *INK4A* locus is frequently mutated in human cancer, particularly in melanoma.

In addition to their role in upregulating p53, ATM and ATR also have a p53-independent role in regulating the firing of DNA-replication origins (see Sect. 2.7.2). Upon perturbations to DNA replication, such as inhibition of DNA polymerase by the drug aphidocolin, ATM (ATR) trigger activation of Chk1 and Chk2, which then inhibit the Cdc25A phosphatase, thereby leading to the inhibition of Cyclin E/Cdk2 and preventing DNA-replication initiation. In addition, ATM and ATR directly phosphorylate components of the DNA-replication initiation complex, the MCM proteins (see Sect. 2.7.2), which is important for these checkpoints to function. The importance of this mechanism is highlighted by the premature DNA-replication origin firing that occurs when ATM (ATR) are inhibited by the drug, caffeine.

In conclusion, the G1 DNA damage and DNA-replication checkpoints provide additional tiers of regulation to the G1-S phase transition, by monitoring the status of the cell so that DNA damage can be repaired and DNA replication can occur faithfully.

2.7 G1-S Cyclin/Cdks and Progression into S Phase

Once Cyclin E/Cdk2 activity has been fully activated and Rb has been phosphorylated and inactivated, the cell becomes committed to enter S phase. Two important events need to occur during S phase: centrosome duplication and DNA replication. The regulation of centrosomal duplication by Cyclin E/Cdk2 and the events occurring at the initiation of DNA replication are discussed in the following.

2.7.1 Centrosomal Duplication

The centrosome (microtubule-organizing center, MTOC) is important for segregation of chromosomes in mitosis, and is duplicated in S phase. The centrosome consists of a central centriole (clusters of microtubules) surrounded by protein matrix, termed the *pericentriolar material*. For the centrosome to duplicate, the centriole first needs to duplicate. The daughter centriole forms in an orthogonal orientation to the mother centriole, by an unknown mechanism. The mother and daughter centrioles then separate and form a pair of centrosomes from the pericentriolar material. Centrosome duplication in vertebrates requires Cyclin E/Cdk2 activity. Constitutive activation of Cyclin E or mutation of p21-Cip1 results in an increase in centrosome numbers. How Cyclin E/Cdk2 results in centrosomal duplication in mammalian cells is presently unclear, but the centrosomal proteins, Nucleophosmin (NPM/B23) and CP110, which are required for centrosome duplication, have been shown to be substrates of Cyclin E/Cdk2. However, a Cdk2-independent role for Cyclin E in centrosomal duplication, by specific localization of Cyclin E at the centrosome has recently been described. This finding is consistent with roles for Cyclin E, distinct from Cdk2 that have been revealed by mouse knockout studies (see Sect. 2.2.1.2). In Drosophila, however, while mutations in SkpA (homolog of Skp1) of the SCF ubiquitin–ligase complex, have supernumerary

centrosomes, this is apparently not due to upregulation of Cyclin E/Cdk2 activity, since *skpA, cyclin E* double mutants still exhibit overduplication of centrosomes. Thus, it appears that there may be differences in regulation of centrosome duplication between Drosophila and mammalian cells.

2.7.2 Initiation of DNA Replication

Studies in the budding yeast, *S. cerevisiae*, have generated a basic model for how duplication of chromosomes is controlled during the cell cycle (see Fig. 17). Genetic analysis in *S. cerevisiae* has identified well-defined origins of DNA replication to which a large prereplicative protein complex (pre-RC) is recruited during the M-G1 phase transition of the cell cycle. Components of the pre-RC have been identified, by genetic and biochemical approaches, and include six origin recognition complex, ORC proteins, six minichromosome maintenance MCM (MCM2–7) proteins, Cdc6, and Cdc45 (see Fig. 17). The ORC proteins remain associated with the replication origin throughout the cell cycle, while other components of the preinitiation complex are sequentially loaded onto origins during G1 phase. Cdc6 is first recruited to origins by an ORC-dependent mechanism. Cdc6 then recruits the MCM protein complex onto DNA-replication origins. In late G1, recruitment of Cdc45 to the pre-RC allows the binding of DNA polymerase-α. Cdc6 is a member of a large superfamily of ATPases known as the AAA^+ family and it exhibits significant sequence similarities to subunits of clamp-loading proteins in eukaryotes (replication factor C complex) and prokaryotes (γ-complex), and may be the loading factor that clamps the MCM protein complex to the DNA. The MCM protein complex has recently been shown to have helicase activity *in vivo* and is required for unwinding the DNA helix at the replication fork during DNA-replication elongation.

The mechanism by which origins are activated is not fully understood, but recent studies have shown that phosphorylation of Cdc45 by Cdk and Cdc7/Dbf4 protein kinases is required for the loading of Cdc45 onto replication origins. Once DNA replication is initiated and a bidirectional replication fork is generated, disassembly of the pre-RC complex occurs, thereby preventing further DNA polymerase-α recruitment and rereplication. In yeast, reinitiation is prevented by mitotic Cyclin B/Cdk activity by maintaining MCMs in a hyperphosphorylated state and inhibiting new synthesis of Cdc6, which is degraded by ubiquitin-mediated proteolysis after origin firing. At the completion of mitosis, inactivation of mitotic cyclin-associated Cdk activity marks the end of inhibitory signals that block new pre-RC formation and allows the pre-RC to reform. Thus, Cdk activity in yeast is responsible for origin firing as well as restricting initiation to once per cell cycle.

Most regulators of replication in yeast such as ORCs, MCMs, Cdc45, and Cdc6 have counterparts in animal cells including Drosophila, although the regulation has not yet been rigorously defined. As in yeast, Drosophila Cdc6 is recruited to the origins in an ORC-dependent process followed by the minichromosome maintenance 2–7 (MCM2–7) protein complex. Later in G1, the recruitment of Cdc45 allows the binding of the DNA polymerase-α at the origin. Recruitment of Cdc45 is dependent on phosphorylation by Dbf4/Cdc7 and in Xenopus the replication initiation factor MCM10 is required after pre-RC assembly and to load Cdc45 onto chromatin. Cyclin E/Cdk2 is subsequently required to allow replication initiation. Indeed, in

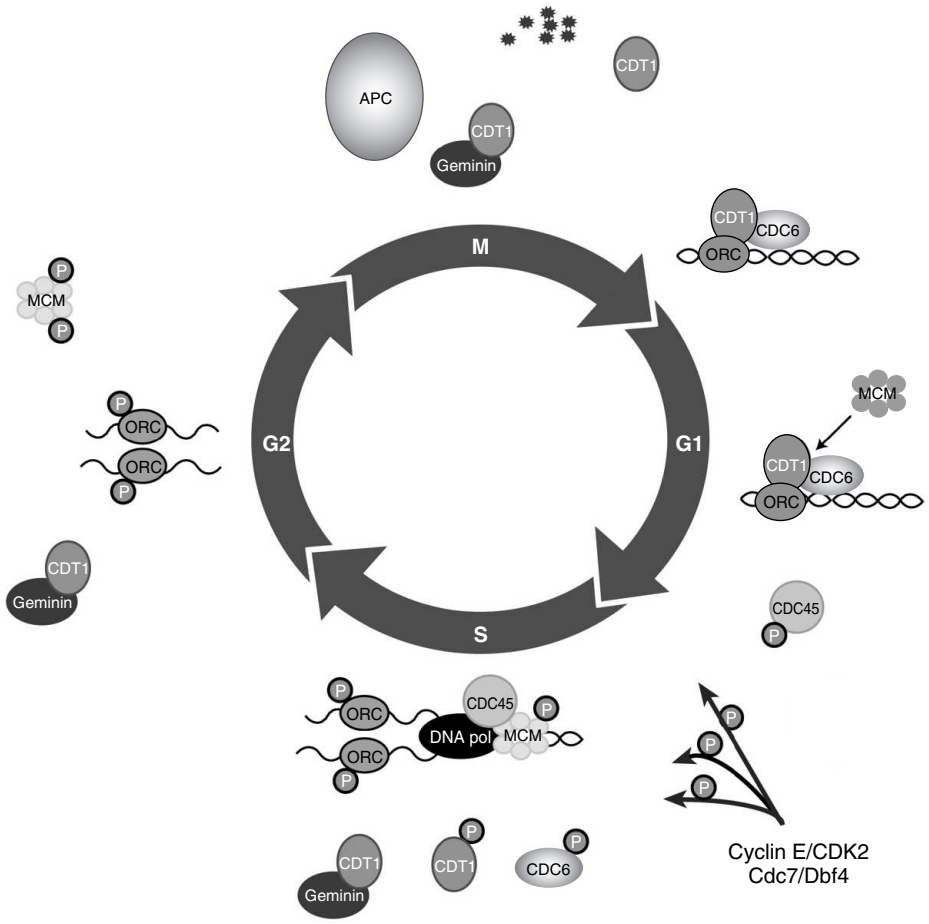

Fig. 17 The initiation of DNA replication. In late G1, origins are first recognized and bound by a six-subunit origin recognition complex (ORC), which remains associated with the origin of replication throughout the cell cycle. In an ORC-dependent process, Cdc6 and Cdt1 are recruited to the origins and are necessary to recruit the MCM2-7 protein complex. Cdc45 can then binds and assemble the prereplication (pre-RC) complex, which allows the binding of the DNA polymerase-α. The CyclinE/Cdk2 and Dbf4/Cdc7 protein kinases are then recruited to the pre-RC complex and trigger DNA replication. After initiation of replication, Cdks phosphorylate Cdc6 and Cdt1, thereby preventing re-replication during S, G2, and M phase. In metazoans, Geminin prevents re-replication during S, G2, and M phase by binding and sequestering Cdt1. Geminin is degraded via the anaphase promoting complex (APC) at the meta-anaphase transition. In this way, Cdt1 allows MCM binding to occur from late mitosis to early S phase.

Xenopus, Cyclin E binds to Cdc6, thereby localizing the Cdk2 complex to chromatin, which is important for DNA-replication initiation. Components of the SCF ubiquitin–ligase complex, including Skp1 and Cul1, are also recruited to chromatin and the preinitiation complex through Cyclin E/Cdk2, and are important in degrading the $p27^{KIP1}$ inhibitor bound to Cyclin E/Cdk2, thereby allowing activation of

Cyclin E/Cdk2 and DNA-replication origin firing.

While most proteins are conserved between yeast and animals, there appears to be considerable differences in regulation of DNA-replication initiation between organisms. One example is the loading of Cdc45 onto pre-RCs. In extracts from the oocytes of the frog, *Xenopus laevis*, phosphorylation of Cdc45 by Dbf4/Cdc7 protein kinase recruits Cdc45 to the pre-RC and Cyclin E/Cdk2 functions after this step to allow initiation, while in yeast, Cdk activity is required before Dbf4/Cdc7. Another example includes differences in regulation of Cdc6. While in yeast, Cdc6 activity is regulated by degradation, its regulation in animal cells is more complex. In human cells, Cdc6 activity requires Cdk phosphorylation in G1, while Cyclin A/Cdk phosphorylation in early S phase results in nuclear-cytoplasmic export. This Cyclin A-dependent event, results in the degradation of free Cdc6, while pre-RC-bound Cdc6 remains stable. Phosphorylated Cdc6 is targeted for ubiquitination by the Skp1, Cul1, F-box (SCF) ubiquitin E3 ligase and subsequently degraded by the 26S proteasome. Therefore, activity of soluble Cdc6 is controlled through G1-S cyclin/Cdk2 activity, while chromatin-bound Cdc6 is constant for most of the cell cycle, suggesting that DNA-replication initiation is not primarily controlled by the presence of Cdc6 on chromatin. In contrast to these findings, *in vitro* studies in Xenopus, suggest that phosphorylation of Cdc6 is not important for either DNA-replication initiation or blocking rereplication.

To explain how DNA replication is limited to once per cell cycle in metazoans, a factor termed *licencing factor* was proposed to permit DNA to become replication-competent after mitosis, but then to be inactivated once DNA replication was initiated, until resynthesized again after mitosis. Recently this licensing factor has been shown to be Cdt1. Cdt1, together with Cdc6, promotes loading of MCMs onto replication origins in M-G1 phase and is inactivated after origin firing in S phase. The majority of Cdt1 protein is rapidly degraded at the G1-S transition. Evidence from several organisms suggests that Cdt1 is targeted for proteasome-mediated degradation by two ubiquitin–ligase complexes, an SCF ubiquitin ligase that contains the specificity subunit Skp2, and an SCF-like ubiquitin ligase that is based on Cul4. The SCF-dependent proteolytic pathway is activated at the G1-S transition, and SCF targets are marked for degradation by Cdk-dependent phosphorylation. In Drosophila, the Cdt1 homolog, Double-parked (Dup) is abundant in G1 when origins are licensed, but is then rapidly degraded when Cyclin E appears at the G1-S transition. This degradation appears to be at least partly regulated through Cyclin E/Cdk2 phosphorylation; however, it seems that additional mechanisms are needed to ensure complete Dup degradation. In human cells, the decrease in hCdt1 protein levels closely mirrors the accumulation of Cyclin A. Indeed, hCdt1 has a consensus site for Cdk phosphorylation, suggesting that hCdt1 may be phosphorylated by a Cyclin A–Cdk complex and targeted for SCF-dependent proteolysis in S phase. The oscillation of hCdt1 protein levels, similar to that of *S. pombe* Cdc18 (the Cdc6 homolog) and Cdt1, may therefore be important for preventing origin refiring in S and G2 phase in human cells.

In metazoans, it has recently been discovered that an additional tier of regulation exists. A novel DNA-replication inhibitor, Geminin, has been identified

in Xenopus, Drosophila, and mammalian cells. Geminin functions as a negative regulator of DNA-replication initiation by binding to Cdt1 and thereby inhibiting the loading of the MCMs. Consistent with Geminin functioning to inhibit Cdt1 and prevent rereplication, Geminin is high in G2 cells, but is degraded in mitosis. In this way, Cdt1-induced MCM binding can only occur when Geminin is absent, at the end of mitosis until early S phase.

2.7.2.1 **Transcriptional regulation of DNA replication.** A key question in understanding DNA replication in metazoans is what determines the timing of DNA-replication origin firing. Global genomic and expression analysis in Drosophila have revealed a strong correlation between gene expression and timing of DNA replication, where early replicating regions correlate with expressed genes and late replicating regions generally correlate with silent genes. Indeed many studies have found correlations between the chromatin state and the firing of DNA-replication origins, suggesting that chromatin-remodeling complexes may play an important role in regulating DNA replication. Recent studies in Drosophila have shown that histone acetylation is an epigenetic event that regulates DNA replication. Acetylated histone H4 colocalizes with ORC2 at times of active initiation of replication in *chorion* genes and is enriched specifically at the origins. Loss of the histone deacetylase (HDAC), Rpd3 by mutation (or by use of an HDAC inhibitor) results in genome reduplication independent of transcription. In addition, Rpd3 and the chromatin-remodeling protein, Polycomb (Pc), locally inhibit DNA replication origin activity, whereas the histone acetylase, HAT1 (Hbo1 in Drosophila) activated origin firing. In mammalian cells, HDAC and the Sin3 HDAC-recruiting complex have been found to associate with the DNA replication and repair protein, Proliferating cell nuclear antigen (PCNA), Replication factor C (RFC), which acts as a clamp loader for PCNA, or with the DNA polymerase-ε complex involved in DNA-replication elongation. Together these data indicate that widespread acetylation may open chromatin and allow DNA-replication origin proteins to gain access to additional binding sites, thereby imparting origin activity in both Drosophila and mammalian cells.

How are these chromatin modifiers recruited to origins? In Drosophila RBF1, dE2F1 and dDP function together at origins of replication to regulate replication of the *chorion* genes during the amplification endoreplication cycles of the ovarian follicle cells (see the following). Indeed, dE2F1 can bind directly to ORC2 at these *chorion* gene origins, and the localization of ORC2 to these origins is prevented in *dE2F1* and *dDP* female sterile mutants. Furthermore, activating mutations of dE2F1 have been identified that have increased replication at the *chorion* gene loci. These mutations remove the binding site for the Drosophila retinoblastoma homolog, RBF1, but also remove the transactivation domain of dE2F1. This shows that dE2F1 has a DNA replication–promoting role at the *chorion* gene loci that is independent of dE2F1s role as a transcriptional activator. This mechanism is not limited to these specialized cycles, since transcription-independent roles for dE2F in inducing S phase have also been documented in the Drosophila eye imaginal disc. Furthermore, this mechanism appears to be conserved as a similar nontranscriptional role in DNA-replication inhibition has been observed

for Rb in mammalian cells. In mammalian cells, Rb binds to MCM7 and inhibits DNA replication and Rb localizes to DNA-replication foci. These studies suggest that the E2F/DP complex plays a direct role at DNA-replication origins which is antagonized by Rb. Finally, mammalian Rb can bind to HDACs and the chromatin-remodeling HDAC complex is recruited with Rb to sites of DNA-replication initiation in mammalian cells. Since the SWI(SNF) chromatin-remodeling complex (Brg1 complex) has been implicated in Rb/E2F-mediated transcriptional regulation with HDACs (see Sect. 2.4), these findings described earlier, now beg the question of whether the SWI(SNF) complex may also be involved in DNA-replication initiation.

The transcription factor DmMyb is another protein that binds to and regulates the activity of *chorion* gene origins in Drosophila. Loss of DmMyb in follicle cells leads to impaired amplification of *chorion* origins despite the presence of the prereplication complex (pre-RC) at the origins. Importantly, recent studies have demonstrated striking similarities between the phenotypes of mutants of DmMyb and its interacting protein Mip130 and that of mutants in dE2F1 and dE2F2. Furthermore, DmMyb and associated proteins are in tight association with RBF1, RBF2, dE2F2 and dDP, and the HDAC, Rpd3. Therefore, DmMyb and dE2F provide a means to differentially recruit chromatin modifiers at *chorion* origins and regulate their activity. These complexes have further been found in Drosophila at stages undergoing genomic DNA replication. It is possible that similar mechanisms also act to regulate genomic replication in mammalian cells.

2.7.2.2 **Alternative modes of DNA replication.** Analyses of Drosophila development have revealed a number of variations to the canonical view of G1-S phase regulation and DNA replication (see Fig. 18). In Drosophila, the early embryonic cell cycles are driven by maternally supplied proteins and mRNA, and occur very rapidly without need for cell growth. Cyclin E becomes limiting at cycle 17, and most cells in the embryo arrest in G1. The upregulation of the CIP(KIP) inhibitor, Dacapo, and the presence of retinoblastoma, RBF1, is also required for the exit of these cells from the cell cycle. After this first G1 phase arrest occurs in embryogenesis, cell growth, and transcription of Cyclin E is required for all further DNA-replicative cycles, such as those of the neuroblasts and imaginal disc cells and to drive a modified replicative cycle, termed *endoreplication*.

Endoreplication, consisting of rounds of S phases without mitosis, occurs in the gut, salivary glands, and other tissues of the developing embryo and larvae and in the adult ovarian nurse and follicle cells. During endoreplication cycles, replication is not complete, leading to amplification of the euchromatic regions of the genome. Endoreplication cycles are driven by *cyclin E* pulses and regulated by dE2F1 and CIP(KIP) homolog, Dacapo, expression. During the follicle cell endocycles, a specialized type of endoreplication occurs, known as *DNA amplification*, where specific regions, such as the *chorion* gene loci are massively amplified. This requires a specialized DNA-replication origin, known as the amplification control element (ACE), a 300-bp sequence that responds to developmental signals to trigger repeated rounds of replication. These endoreplication and amplification cycles are important to allow increased protein production for either rapid larval growth or production of an oocyte in the adult

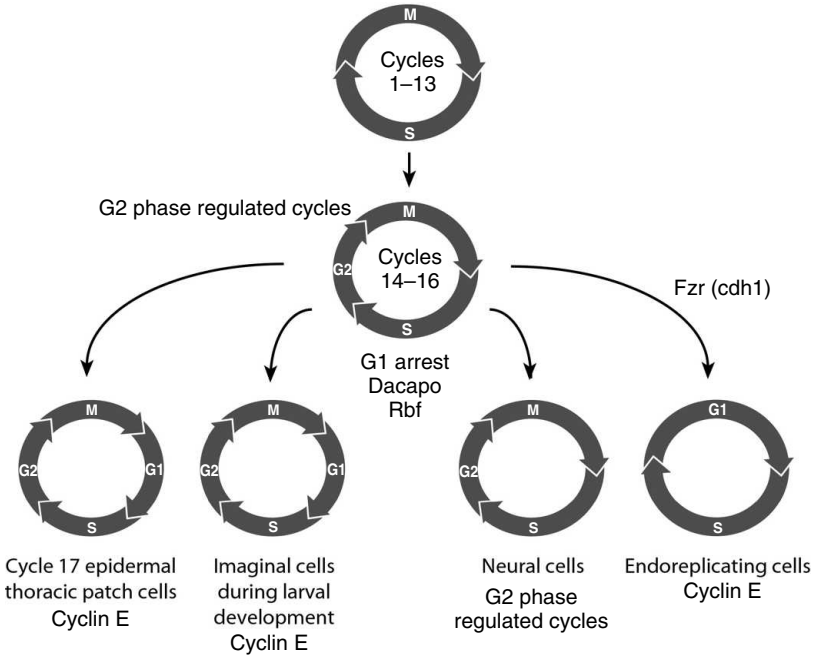

Fig. 18 Alternative modes of DNA replication in Drosophila development During Drosophila development, there are different modes of cell cycle regulation at different stages and in different tissues. During early embryogenesis, cell cycles are very rapid due to the high levels of maternally supplied proteins. Later in embryogenesis, G2 regulators become limiting and cell cycles are controlled by the cyclic synthesis of G2 regulators. Cyclin E becomes limiting at cycle 17, and most cells in the embryo then arrest in G1. The upregulation of Retinoblastoma (Rbf) and the $p21^{CIP1}$ ($p27^{KIP1}$) homolog Dacapo is also required for the timely arrest of these cells in G1. Cyclic transcription of cyclin E then drives cell cycle progression of certain cell types, such as those of the cycle 17 patch and imaginal discs. Cyclin E is also essential for switching from the canonical cell cycle to endoreplication, which consists of cycles of alternate DNA replication phases without mitoses. Upregulation of Frz (Fizzy-related/Cdh1), a regulator of the anaphase promoting complex (APC) ubiquitin ligase, is required to degrade G2 regulators and for switching the mitotic cycles to endoreplication cycles.

female. In the mouse, endoreplication cycles occur in the trophoblast cells of the placenta during development, which is important for the function of the placenta. These cycles are also highly dependent on Cyclin E, although Cyclin E can be redundant in most other cell cycles (see Sect. 2.2.1.2).

Studies of the follicle cell epithelium of the Drosophila ovary have shown that the Notch signaling pathway controls the follicle cell mitotic-to-endocycle transition by stopping the mitotic cycle and promoting the endocycle. Downregulation of the G2-M phosphatase Cdc25(String), occurs in response to Notch signaling and is required for the mitotic-endocycle transition. In a screen for genes whose transcription was markedly changed at the mitotic-endocycle transition, the growth regulator

dMyc, the CDK inhibitor Dacapo and the APC ubiquitination complex regulator, Fizzy-related (Fzr, Hec1, Cdh1) were identified and shown also to be important for the mitotic-endocycle transition. Upregulation of Fzr leads to degradation of G2-M phase regulators, such as Cyclin A, Cyclin B, and Cdc25(String), thereby preventing cells that have replicated their DNA from entering mitosis. Although not required for mitosis, Fzr is essential for endocycles and when expressed prematurely during mitotic stages, Fzr is sufficient to stop the mitotic cycle and can promote ectopic endocycles. Similarly, in embryogenesis, for endocycles to initiate, G2-M cell cycle components need to be degraded, which is mediated by the upregulation of Fzr. Downregulation of Dacapo at the mitotic-endocycle transition is consistent with the observation that higher levels of Dacapo are required in the oocyte during the early stages of oogenesis, to ensure that the oocyte stays in meiotic prophase. Indeed, ectopic overexpression of Dacapo prevents entry into the endocycle and *dacapo* mutant oocytes precociously enter the endocycle.

Consistent with the involvement of the Notch pathway in the mitotic cycle-endocycle switch, Notch signaling is required for downregulation of Dacapo and for upregulation of Fzr expression. Indeed, persistent expression of *dacapo* occurs in the Notch signaling mutant, *Delta*. Therefore, Notch signaling regulates the mitotic-to-endocycle switch by coordinating all three major cell cycle transitions; first by repression of *cdc25* (*string*) expression, next by activation of Fzr leading to degradation of Cyclin A and Cyclin B thereby blocking mitosis, and lastly by repression of Dacapo which allows Cyclin E/Cdk2 to drive S phase entry.

dMyc was also identified as being transcriptionally upregulated at the mitotic-endocycle transition and, consistent with this, a recent study has shown a role for dMyc in regulation of ovarian follicle cell endoreplication. A role for dMyc in regulating larval endoreplication has also recently been reported. In addition, Archipelago (Ago), the F-box component of the SCF ubiquitin ligase, was found to be essential for Cyclin E degradation and endocycle progression in the follicle epithelium. Ago also plays a role in dMyc degradation (see Sect. 2.4.3), suggesting that ubiquitin-mediated proteolysis via the Ago-SCF may regulate dMyc protein levels in the mitotic-to-endocycle transition.

In summary, during Drosophila development, the canonical DNA-replicative cycle can be modulated by altering expression of key cell cycle regulators. These variations in the cell cycle regulatory modes have not been well studied in tissues known to undergo endoreplication in mammals; however, it is expected that similar types of regulation will occur. Indeed the variation in G1-S phase regulation in mammalian cells is only now being appreciated. The best characterized example to date is the Embryonic Stem (ES) cell cycle. The ES cell cycle is one of the most rapid cycle so far described in mammals with ES cells undergoing cycle in under 6 hours in vitro and for their equivalent population in vivo, the inner cell mass of the blastocyst, under 4.5 hours. This cell cycle is unusual in that it is characterized by extremely high levels of cyclinE/Cdk activity that lack normal cell cycle periodicity, resulting in low activity of Rb-family proteins and the constitutive activation of E2F-dependent gene transcription thus ensuring a rapid G1-S transition. Periodicity of the cell cycle is ensured by regulated activation of cyclin B/cdc2 activity.

3 Summary and Future Directions

We have highlighted here, the circuits of controls required to regulate the transition from G1 into S phase. The cell cycle needs to be tightly regulated to ensure proper duplication and segregation of chromosomes into daughter cells. This is highly important, since loss of cell cycle regulation can lead to genomic instability and promote chromosome loss (aneuploidy), which can result in the development of tumors.

Studies in yeast and mammalian cultured cells have provided a detailed picture of cell cycle control in single cells; however, it is becoming increasingly clear in multicellular organisms that cell cycle regulators can play redundant roles and different regulatory steps are emphasized at different stages of development. Thus, to fully elucidate the myriad of regulatory circuits that occur *in vivo*, and to more clearly understand proliferative disorders, such as cancer, future research needs to focus more on whole animal genetic studies and use of more sophisticated animal models.

Keywords

Cell Signaling
A group of molecular mechanisms that relay external stimuli to molecular machinery within the cells. This can be achieved via interactions between similar or different classes of proteins, or between proteins, peptides, ions, or even nucleic acids.

Chromophore
A chemical moiety that absorbs light in some, but not all, regions of visible spectrum, thereby creating color appearance. If the absorbed light energy is subsequently reemitted also in the form of light (i.e. fluorescence occurs), the moiety is called fluorophore.

FACS
Fluoroscence-activated cell sorter, a device that separates different cells on the basis of their fluorescence.

Fluorescence
The ability of a chemical to absorb light at one wavelength (the excitation wavelength) and to reemit the light (fluoresce) at another specific but longer wavelength.

FRET
Fluorescence resonance energy transfer, a radiationless transfer of excitation energy from one (donor) fluorophore to another (acceptor) fluorophore. This transfer is possible due to overlap of donor's emission and acceptor's excitation spectra and the close proximity of the two fluorophores.

Transgenic Organisms
Animals or plants that carry artificially introduced gene(s) that are stably integrated into the host genome and passed to future generations.

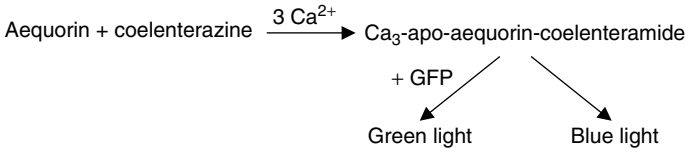
Green fluorescent protein (GFP) possesses unique biochemical and biophysical properties that make it a popular and powerful tool for both basic and applied research. Originally isolated from jellyfish, its gene can be introduced to various host species and results in a stable protein that can form matured chromophore without the need of other cofactors and enzymes. Various wildtype and mutant forms of GFP have been identified through protein engineering or the search for similar proteins in other species such as reef corals and their relatives. With unique properties, they offer excellent markers for monitoring various biological processes in a single cell or whole organism. These include viewing of the internal structure and protein movement as well as studies of protein–protein interaction. As a transgene, it is also very useful for monitoring developmental process and as a promising source of genetically modified ornamentals. Coupled with advanced bioimaging methods, GFP and its variants are expected to continue to provide new insights into many biological processes.

1
The Historic Background of GFP

1.1
Jellyfish and GFP

During the course of evolution, some species such as bacteria, mushrooms, dinoflagellates, jellyfish, earthworms, squids, fireflies, shrimps, and flashlight fish, have all adopted various forms of bioluminescence to serve certain biological functions that are important for their own survival. Bioluminescence is the process by which visible light is emitted by an organism as a result of chemical reaction after the oxidation of a substrate (luciferin) by an enzyme (luciferase) that usually requires oxygen as the oxidant. Such a mechanism is employed as a part of the organism's strategies in defense (to deter predators), offense (to help in predation), or communications (such as during courtship or mating). Understanding the biochemistries for different classes of such compounds had set the stage for a key revolution in science.

Studies on the bioluminescence of the jellyfish *Aequorea victoria* (also known as *Aequorea aequorea* or *Aequorea forskalea*) dated back to the mid 1950s. Then, Davenport and Nicol reported that the light-producing cells of the jellyfish fluoresced green when the animal was irradiated with ultraviolet light. Five years later, Frank Johnson and Osamu Shimomura developed a protocol to extract the active light emitting particle of the jellyfish, a substance they later named *aequorin*. In their earlier classic work, they reported on the ability of aequorin to emit blue light in the presence of Ca^{2+} and exhibited a broad spectrum with peak at 460 nm. During the purification of aequorin, they noticed the presence of yet another protein that, according to their report, was ". . . . exhibiting a very bright, greenish fluorescence in the ultraviolet of a Mineralite. . . . " Such *green protein*, having a sharp spectrum instead and with an emission peak at 508 nm was termed *green fluorescent protein* (GFP). This demonstrated that light organs of the jellyfish contain the aequorin and GFP, perhaps allowing the jellyfish to be more



efficient in triggering visual responses as the green corresponds to the region of maximum sensitivity of the eyes of the animals adapted to living in coastal waters. The most interesting findings, then, were the observations that aequorin could exist as a complex with GFP upon binding with Ca^{2+} and the oxidation of its luciferin, coelenterazine, although it itself was not directly bound to the GFP. *In vitro*, such complex of Ca^{2+}-apo-aequorin-coelenteramide emits blue light, but *in vivo*, it is believed that this complex undergoes radiationless energy transfer to GFP that gives off green fluorescence as indicated above:

Subsequently, GFP homologs have been found in numerous organisms and many mutant forms have been generated. Since the GFP from the jellyfish *A. victoria* is best studied at the biochemical and molecular levels, and is also the most commonly used for the tracer studies, it serves as the focus of our discussion. However, due to its diverse forms and applications, we have used the word "GFP" loosely to include the natural form, mutants, or its homologs that may produce different spectra. Since the cloning of the GFP cDNA from *A. victoria* in 1992 and the introduction of GFP cDNA as a living color-reporter gene in both prokaryotic (*Escherichia coli*) and eukaryotic (*Caenorhabditis elegans*) cells in 1994, the scientific research on GFP and its applications have rapidly expanded, as witnessed by the dramatic increase of literature containing the key words *green fluorescent protein* or GFP (Fig. 1). It provides an important tool in many disciplines of life science research in both prokaryotes and eukaryotes – from cellular and molecular biology to neurobiology; from developmental biology and molecular medicine to food industry. Several major breakthroughs are highlighted (Table 1) some of which will be covered in the text below. Coupled with

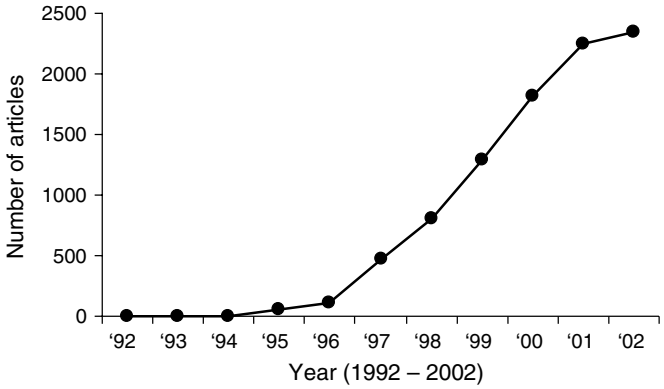


Fig. 1 Number of articles reporting on GFP, retrieved by *green fluorescent protein or GFP* query search in science citation index.

Tab. 1 Chronicle of research on GFP and its applications.

Year	*Events*
1955	Observation that *Aequorea* fluoresced green when irradiated with ultraviolet light
1969	One of the earliest biochemical characterization leading to coining the word ''green fluorescent protein''
1979	Chemical structure of chromophore deduced
1992	Cloning of GFP cDNA and deduced GFP primary structure
1993	Chemical structure of GFP chromophore confirmed
1994	GFP as a reporter gene in *E. coli* and *C. elegans* Expression of GFP fusion protein in *Drosophila*
1994–1996	Mutations on GFP that generates different spectral properties, including the Blue Fluorescent Protein (BFP), Cyan Fluorescent Protein (CYP) and Yellow Fluorescent Protein (YFP)
1995	GFP transgenic plant, zebrafish and mouse
1996	First crystal structures of wildtype and mutant GFP solved
1997	Use of GFP to recapitulate gene expression patterns in living transgenic zebrafish
1997–1998	FRET-based GFP reporter as biosensors and tools for studies of protein–protein interaction
1998	pH-sensitive mutant ''pHluorin'' used in visualization of secretion and synaptic transmission; GFP knock-in mice Destabilized GFP as transcriptional reporter
1999–2001	Discovery of fluorescent proteins from nonbioluminescent corallimorph *Discosoma sp.* (DsFP583/DsRed) and from the sea anemone *Heteractis crispa* with far-red-emitting mutant of nonfluorescent blue chromoprotein (hcriGFP/HcRed); multispectral imaging is feasible. Mutant form of DsFP583 is used as ''fluorescent timer.''
2002–2003	Development of ''photoactivatable probes.'' Use in live-cells kinetics imaging for signaling metabolites or proteins in single cell or larger population, and for cell lineage studies.

advances in bioimaging methods and the discoveries of more variants with readily distinguishable spectra and improved properties, many more experimental approaches are expected to provide new insights into many biological processes.

1.2 Cloning of GFP cDNA

The first wave of GFP *Green Revolution* was initiated by the cloning of the complementary DNA (cDNA) from *A. victoria* and its deduced primary sequence by Prasher et al.. It encodes a protein of 238 amino acids, with an estimated molecular weight of 27 kDa. This has allowed scientists to carry out extensive molecular and structural biology work to elucidate the structure–function relationship for GFP that laid the foundation for the development of GFP technology. In 1994, Chalfie et al. had introduced the GFP cDNA into heterologous systems and produced a fluorescent product in both bacteria and *C. elegans*. Their findings demonstrated that single polypeptide was sufficient to confer fluorescence without exogenous substrates and cofactors, thus confirming the earlier notion that autocatalytic cyclization of the chromophore formation was involved. More importantly, their results elegantly showed that GFP expression could be used to monitor gene expression and protein

localization in living organisms, which are later extensively used either as a coexpression marker or fusion proteins. This had created tremendous excitement among the scientific community and a ''star'' was truly born.

2 Biochemical and Physical Properties of GFP

2.1 Physical Characteristics of GFP

We have seen rapid expansion of GFP applications. To provide further improvements by protein engineering, one needs to understand the biochemical and physical properties of the GFP molecule and its chromophore. This will facilitate our hunt for better versions of GFP that promises enhanced contrast in fluorescence detection either by means of changing the biophysical properties or improvement in terms of their gene expression, protein synthesis and folding, or its photostability. This is also important so as to provide a sound basis for the quantitative and qualitative interpretations of data generated in its applications.

Cloning of GFP cDNA and its successful expression as a recombinant protein has allowed production of high amounts of pure form of GFP for extensive biochemical and physical studies, including its structural studies. As expected, most of the biochemical and physical studies were performed on this *Aquorea wildtype* form, *Aequorea victoria* green fluorescent protein (AvGFP) and the sea pansy, *Renilla reniformis* (RrGFP), as well as their mutants, while minimal information can be obtained from 20 other naturally occurring GFPs – usually with nothing more than just the wavelength of peak emission.

All known GFPs are acidic, compact, and globular with monomer molecular weight of 27 kDa. Some, for example, RrGFP, could exist as a nondissociable dimer unless denatured or diluted in aqueous solution whereas AvGFP forms a weak dimer with the dissociation constant of 0.11 mM. They are generally very stable, an obvious advantage as a reporter of gene expression. The core of the protein is highly resistant against proteolysis, but the carboxyl terminus of the AvGFP (His-Gly-Met-Asp-Glu-Tyr-Lys) is quite susceptible to attack by carboxypeptidases. Furthermore, the presence of two basic residues (histidine and lysine) and two acidic residues (aspartic acid and glutamic acid) can cause partial proteolytic cleavage that generates mixture of isoforms.

The T_m (temperature where half of the endogenous fluorescence is lost) for AvGFP and RrGFP is 76 °C and 70 °C respectively. While the fluorescence of RrGFP is unaffected over a wide pH range and is stable at its isoelectric point (pH 5.34), AvGFP is less stable at its isoelectric point (pH 4.7 to 5.1). Furthermore, AvGFP is different from RrGFP when placed under alkaline conditions such that there is a drastic shift in its excitation spectra. Interestingly, there are no significant changes in the excitation or emission spectra of GFP after treatment with anionic, cationic, zwitterionic, or nonionic detergents indicating a general rigid tertiary conformation. Overall, GFP is very resistant to denaturation, requiring treatment with 6 M guanidinium hydrochloride at 90 °C or under very acidic (pH < 4) or basic (pH > 12) conditions.

2.2 Three-dimensional Structure of GFP

The crystal structure of recombinant wildtype and Ser65Thr (substitution of

the amino acid serine by threonine at position 65) mutant of AvGFP was solved to a resolution of 1.9 Å by Yang et al., and Ormö et al. respectively. They revealed various structural aspects of GFP that explain some of the known biological behavior of this molecule and would allow a better rational design of mutants for future development of this tracer molecule. Overall, GFP presents a new protein fold termed *beta-can* (Fig. 2a, 2b).

The cylinder has a diameter of about 30 Å and a length of about 40 Å. There are 11 antiparallel beta strands forming the core of the very compact cylinder inside which there is a helix bearing the chromophore. At the end of the *can* are several short helixes. Such a compact single-domain structure with the chromophore centrally located protects itself from bulk solvent. This could explain why GFP is relatively stable and inaccessible to classical quenching agents such as acrylamide and molecular oxygen, resulting in the high quantum yield of fluorescence. At both the ends of the *can* are short loops and distorted α-helices. Interestingly, deletion of more than the methionine at N-terminus or more than seven amino acids from C-terminus leads to a severe loss of fluorescence without the typical spectrum of absorption, probably due to the improper folding of the *can*. Furthermore, two GFP proteins can also pack closely together to form a dimer in the crystal or in solution at low ionic strengths. Dimerization can affect the excitation spectra and energy transfer of GFP, thus the identification of the dimer contacts could allow mutagenic control of the state of assembly of the protein.

Since the first reports, structures for various mutant forms as well as the homologs of GFP from other species have also been solved, each presenting a conserved beta-can structure. They have provided important information on the key residues that affect the general or specific properties of GFP family proteins so as to allow further fine-tuning through genetic and protein engineering.

2.3 Chromophore of GFP

Colors originate from differential scattering of light or display of colored molecule – either by biochrome or pigments, or both. Their syntheses require multiple steps of sequential reactions catalyzed by a specific enzyme(s) and require certain cofactors. GFP represents a unique system where it is both the substrate and enzyme. Its chromophore is a product of modification of its own backbone and sidechains and is covalently bound within the protein. Indeed, the lack of dependency on multienzyme systems provides this *all-in-one* enzyme a unique advantage as an inconspicuous indicator of protein position in cells.

The first small peptide fragment containing the chromophore of GFP was isolated from a papain digest of heat-denatured GFP. The structure proposed, which was subsequently confirmed, comprises an internal Phe64-Ser-Tyr-Gly-Val-Gln69 sequence that is posttranslationally modified via an intramolecular autocatalytic cyclization to form a 4-(*p*-hydroxybenzylidene)-imidazolid-5-one structure (Fig. 2d). The formation of the chromophore involves a sequential, autocatalytic mechanism. The reaction is initiated by a rapid cyclization between Ser65 and Gly67 to form an imidazolin-5-one intermediate that is followed by a much slower rate-limiting oxygenation of the Tyr66 side chain by O_2 on a timescale of hours. Gly67 is required for the formation of chromophore;

(e)

no other amino acid can replace glycine in this role, as seen by its conservation in different members of the GFP family (Fig. 2e). Oxygen molecules are then needed for the formation of the double bond between two carbons on the tyrosine to form an extended aromatic system. However, despite its requirement, the oxygen must be excluded from interacting with the chromophore itself to avoid collisional quenching of the fluorescence. Two resonant forms of the chromophore can be assumed: one with a partial negative charge on the benzyl oxygen of tyrosine and the other with the charge on the carbonyl oxygen of the imidazolidone ring. They can be stabilized by some of the positive charges developed by His148, Gln94, and Arg96 in the GFP itself. The fluorescence is not an intrinsic property of the Ser-Tyr-Gly tripeptide as this sequence can be found in quite a number of other proteins, none of which has the fluorescence.

With the discovery of several GFP-like molecules, it is a pleasant surprise to learn that there exist variations in the mechanisms of reactions. Thus far, at least 4 different color classes of GFP-like proteins can be distinguished from each other: green, yellow, orange-red and nonfluorescent purple-blue or chromoproteins. Interestingly, each class can apparently synthesize its own chromophore with several possible variations of pathways but none of these naturally occurring proteins has utilized any of the spectral-shifting solutions identified in mutant variants of GFP from *A. victoria* (see Sect. 2.4). Phylogenetic analyses also indicate that these chromophore structures are very recent entities and not the products of prolonged evolutionary fine-tuning. Coupled to the overall conservation of the beta-can folding of the GFP-like polypeptides, it is believed that the catalytic environment in GFP family proteins is *flexible* to accommodate switches between alternative pathways of chromophore formation during the course of evolution.

2.4 Genetically Modified GFP and its Natural Homologs

The fluorescent behavior of GFP depends greatly on the microenvironment surrounding the chromophore. Most of the polar residues in the pocket form a hydrogen-bonding network on the side of Tyr66 whereas atoms in the side chains of Thr203, Glu222, and Ile167 are in van

Fig. 2 Structure of GFP. der Waals contact with Tyr66 . Therefore, any mutations of these residues could have direct steric effects on the chromophore, thus the absorption and emission spectra of the GFP protein. Some mutations have significant wavelength shifts and most suffer a loss of fluorescence intensity.

To date, many random and directed point mutations have been introduced into AvGFP and have resulted in various changes in its fluorescent behavior (Table 2). Some of these improved characteristics are combined in the GFP variants known as enhanced GFP (EGFP) and are exceptionally bright and stable and are widely used in many applications nowadays. Subsequently, other mutants of AvGFP such as Blue Fluorescent Protein (BFP), Cyan Fluorescent Protein (CYP) and Yellow Fluorescent Protein (YFP), were derived with further improvement and distinctive properties useful for multicolor imaging as well as Fluorescence Resonance Energy Transfer (FRET) studies (see Sect. 3.2). Some mutants have increased fluorescence with their major excitation peak red-shifted to 490 nm with the emission staying at 509 nm. This is better for use with standard optical filter sets, as the mutant GFPs have excitation range more compatible with the commonly available optical filters. This is also more useful in confocal laser scanning applications.

Efforts to further red-shift AvGFP spectra to produce additional partners for multispectral experiments have had little success. Fortunately, some marine organisms have provided alternative fluorescent proteins to the red-wavelength range. These include a class of Anthozoan naturally fluorescent proteins that share 26 to 30% identity to the AvGFP. Among them is DrFP583 (better known as *DsRed* commercially) from the corallimorph *Discosoma* and the DsRed mutants. The sea anemone *Heteractis crispa* also offers another important source of alternative, the HcRed, which itself is a fluoresecent mutant of an original nonfluorescent blue chromoprotein cloned from this species. Each of them has emission peaks ranging from 579 to 645 nm, making multispectral imaging very feasible (Fig. 3). For instance, the HcRed that exhibited bright emission at 645 nm could be excitable by 600-nm dye laser, thus promoting new detection channels for multicolor flow cytometry applications. Furthermore, successful attempts were made in decreasing dimerization of these GFP variants at high concentrations. To date, about 30 significantly different members of *GFP-like proteins* have been identified and more discoveries are expected to follow. Despite a modest degree of sequence identity, all of them are likely to share similar β-can folding and possess intrinsic chromophores. While most of these GFP-like proteins are themselves fluorescent proteins, some are chromoproteins that display only intense absorption without fluorescence emission.

Following structural and mutagenic studies that have provided powerful insights into not just the mechanism of its chemistry but its potential for further development of more versatile GFPs, we have recently seen several new forms of GFPs or the GFP-like homologs being introduced, each capitalizing on the improved or unique labeling performances well as optimized for expression in eukaryotic system. They include, the *Ace-Green* expression vectors, encoding novel bright green fluorescent protein AceGFP (mammalian, *Dictyostelium* and *C. elegans* codon usage optimized); the *HcRED tandem* expression vectors, encoding the first commercially available nonoligomeric far-red

Tab. 2 Spectral properties of GFP and selected variants from *Aequorea victoria* or homologs from *Aequorea coerulescens, Discosoma* sp. and *Heteractis crispa*.

Fluorescent protein	***Source***	***Excitation/emission (nm)***	***Main properties and key mutations***
avGFP (wildtype)	*Aequorea victoria*	395[a], 475 / 507	The first GFP cloned and characterized. The template from which many other variants are derived.
EGFP (Enhanced GFP)	*Aequorea victoria*	489 / 507	Phe64Leu, Ser65Thr, red-shifted, accelerates speed of chromophore formation and elevates temperature sensitivity and humanized codon usage; increases fluorescence by 40-fold in mammalian cells; excitation peak nears the 488 nm laser line for confocal microscopy.
Destabilized GFP	*Aequorea victoria*	489 / 507	Reduced halflife with the PEST degradation domain of mouse ornithine decarboxylase at the C-terminal end of an EGFP; used to directly correlate gene induction with biochemical change
pH-sensitive GFP (pHluorin)	*Aequorea victoria*	395, 475 / 507	Two classes of mutants, one with maximum excitation peak that shifts to 475 nm as pH decreases (ratiometric pHluorin) and the other gradually loses fluorescence as pH decreases (ecliptic pHluorin). Both classes contain a common Ser202His mutation plus other unique composite of mutant residues; used for visualizing secretion and synaptic transmission; also used in plants for biomonitoring
AceGFP	*Aequorea coerulescens*	280, 390[a] / 460, 505	Derived from a colorless GFP-like protein from *Aequorea coerulescens* (acGFPL); a novel mutant (Glu222Gly substitution) for UV-induced photoconversion from an immature nonfluorescent form into a green fluorescent form.
BFP (Blue FP)	*Aequorea victoria*	384 / 448	Tyr66His, first used for multicolor imaging but it is dim and readily photobleached
CFP (Cyan FP)	*Aequorea victoria*	433 / 475	Tyr66Trp, blue-shifted, brighter and greater photostability than BFP; good dual color-imaging and FRET partner with YFP
YFP (Yellow FP)	*Aequorea victoria*	514 / 527	Ser65Gly and Thr203Tyr, red-shifted, brighter than EGFP but more sensitive in low pH and high halide concentrations, and photobleaching

(*continued overleaf*)

Tab. 2 (*Continued*)

Fluorescent protein	*Source*	*Excitation/emission (nm)*	*Main properties and key mutations*
DrFP583 (DsRed)	*Discosoma sp.*	558 / 583	Extending to red spectral range; slow maturation (>10 h) and self-associated to tetramers. A mutant form is used as ''fluorescent timer'' where initially it emits green fluorescence followed by red fluorescence
mRFP1	*Discosoma sp.*	584 / 607	Less bright than DsRed and photobleaches more easily, but faster maturation and no self-association
HcRed	*Heteractis crispa*	592 / 645	Derived from nonfluorescent chromoprotein and has far-red shifted spectra. Optimized for high solubility and rapid maturation through mutations, hence early detection. Tetramer in nature but mutant can form dimers that are preventable by expression in tandem; very useful for multicolor analyses when combined with cyan, green, yellow fluorescent proteins
PA-GFP	*Aequorea victoria*	400 (preactivation)/515 502 (postactivation)/517	Val163Ala and Thr203His. Improving photoconversion from neutral to anionic species. Photoactivable to give 100-fold increases in green fluorescence
Kaede	*Trachyphyllia geoffroyi*	508 (preactivation)/518 572 (postactivation)/582	Kaede exhibits remarkable 2000-fold increase in red-to-green fluorescence. However it requires around 400 nm light for photoactivation and it could form oligo-tetramers
KFP1	*Anemonia sulcata*	580 (preactivation)/600 580 (postactivation)/600	Mutant generated from a chromoprotein. Red fluorescence increases by 30-fold upon green irradiation – ''kindling'' with reversible photoactivation. It can also self-associate.

[a]Indicates major peak.

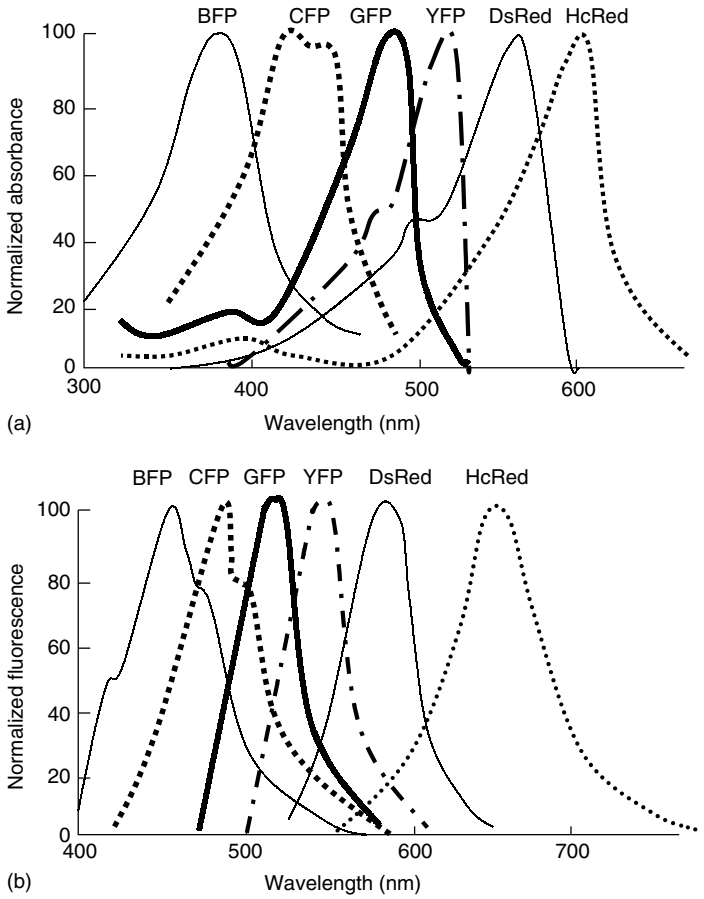

Fig. 3 The normalized absorbance (a) and emission (b) BFP, CFP, GFP, YFP, DsRed and HcRed fluorescent proteins.

fluorescent protein t-HcRed especially designed for protein localization and interaction studies. The other one, Kindling-RED *in vivo* tracking vectors, encodes unique photoactivated red kindling fluorescent protein (KFP-RED) that may be switched from nonfluorescent to fluorescent form by light. Some of the photoactivatable fluorescent proteins and their properties are described and discussed in more detail in Sect. 3.1 below. Some of the properties for these GFP-like proteins were recently reviewed by Miyawaki and Matz et al., highlighting the emerging prospects of GFP-like proteins in the wide spectrum of biotechnological applications, some of which will be discussed within the context of GFP applications below.

3 Applications of GFP Family Proteins

The wide applications of GFP family proteins are mainly attributed to their ability to form the chromophore via an internal autocatalytic cyclization without

external substrates and cofactors. This also bypasses the regulation by multiple enzymes. Furthermore, its relatively stable structure and inert behavior such as low or nontoxicity in cells and the lack of interference in the fusion proteins' activity and mobility makes it an even more attractive tool to use. With the availability of various mutants and homologs, some of them have been engineered to be optimized for use in certain hosts (through codon usage), while others can be made to change in their half-lives and fluorescence spectra with time (as fluorescent *timers*). These and other unique advantages have made GFP and other GFP-like proteins as some of the most versatile tools used in the modern day research. Some of their applications are given in the sections that follow.

3.1 GFP as a Reporter of Gene and Protein Expression

Understanding the timing of gene expression and the protein dynamics are very crucial for assigning the physiological function of a protein, especially when we want to understand how its expression and activity relate to the presence of other molecules in the cell. *GFP* was first used as a reporter gene in transgenic *C. elegans*. Various forms of GFP are now available for such studies, including mutant variants with different spectral properties (see Sect. 2.4) or other homologs such as the DsRed from the corallimorph *Discosoma*. Use of variants allows simultaneous visualization of multiple fusion proteins in a cell or multiple cell types in tissues. In gene-expression profiling, multicolor fluorescent proteins help to detect different aspects of gene expression. For example, when the peroxisome-targeted cyan fluorescent proteins (CFP) cDNA was linked to the *lac* operator site and coexpressed with the yellow fluorescent protein (YFP)-fused *lac* repressor, were able to observe the concerted transcription, marked by visible decondensation of YFP-associated chromatin and translation, as seen with an accumulation of CFP signals in the peroxisomes.

However, the relatively stable structure of GFP makes it difficult to accurately monitor the temporal sequence of reaction in cells or tissues as residual signals from the earlier process could mask the subsequent events. To decrease the half-life of GFP, Li et al. inserted a PEST-containing protein domain to the carboxyl terminus of GFP and showed that the new fusion could be rapidly degraded. While such *destabilized* GFP reporters are more difficult to detect, they do provide an excellent means to effectively quantify some processes such as the ubiquitin-mediated proteolytic process.

Another excellent example where modified GFP is used for temporal studies involves a fluorescent protein whose spectral properties change with time. This was generated by random mutations of the red fluorescent protein DrFP583 (DsRed). In contrast with the analogous GFP-based techniques, multiphoton bleaching of DsRed does not abolish its fluorescence completely but, instead, converts it from red to green, thus providing an additional way to regulate the process of fluorescence redistribution. Such a *fluorescent timer* produces green fluorescence initially but hours later, an oxygen-dependent autocatalytic reaction drives the formation of chromophore that emits red fluorescence. Therefore, by measuring the ratios of red to green one could determine whether the

expression is nascent (yellow to orange appearance) or has already stopped (appears entirely red).

Several other promising approaches to studying protein lifespans and turnover rates involve the use of photoactivatable fluorescent proteins, or the use of photobleaching-based kinetic microscopy techniques. Photoactivatable fluorescent proteins exhibit little initial fluorescence under excitation at the imaging wavelength but their fluorescence increase following the activation by irradiation at a different wavelength. The outcomes are direct display of specific populations of molecules in the cells, where the behavior and lifespans of the selective photoactivated molecules are studied independently of other newly synthesized proteins. The short time required for photoactivation (in some cases, less than 1 second) makes it potentially useful for investigating the movement and compartmental residency time of proteins.

To date, three forms of photoactivatable fluorescent systems have been developed; each one is based on different proteins and with different principles. One of these, PA-GFP was developed by improving the wildtype AvGFP photoconversion from a neutral to anionic species by the Thr203His mutation. It was based on the same excitation spectra change effect (increase in the 488-nm peak at the expense of a decrease in the 400-nm peak) with a remarkable 100-fold improvement in contrast. Furthermore, PA-GFP was developed using the monomeric GFP that is useful as a fusion tag for *in vivo* labeling. Such photoactivatable GFPs were tested both as a free protein to measure protein diffusion across the nuclear envelope and as a chimera with a lysosomal membrane protein to demonstrate rapid interlysosomal membrane exchange.

The second system was developed by Ando et al. who cloned a gene that encoded a fluorescent protein from a stony coral *Trachyphyllia geoffroyi* that emits green, yellow, and red light. The protein, which was serendipitously discovered as a result of someone accidentally leaving a test tube of the fluorescent protein overnight that turned red the following day, was named *Kaede*, the Japanese word for "maple leaf". Kaede includes a tripeptide, His-Tyr-Gly, which acts as a green chromophore that can be converted into red under UV or violet light (350–400 nm). It acts by exciting the protonated form of the chromophore. The extensive diffusion of Kaede allowed them to examine a single neuron in a dense culture where visualization of contact sites between the red and green neurons of interest becomes possible. Although this system allows bright and stable emission of red fluorescence, it however has a disadvantage by employing damaging UV light. Moreover, the tetrameric nature of the Kaede protein as well as the use of both green and red fluorescence makes it less versatile for studies of fusion proteins and multicolor labeling. Recently, Campbell et al. have converted DsRed into a monomeric red fluorescent protein (mRFP1) in a stepwise fashion. On the basis of the homology between Kaede and DsRed, similar semirational attempts are being made to develop a monomer of the Kaede for use in Kaede-fused proteins to monitor protein trafficking.

Both PA-GFP and Kaede protein do not allow reversible photoactivation that is ideal for certain applications, especially in fast processes. More recently, Chudakov et al. generated a mutant of *Anemonia sulcata* chromoprotein asCP that is capable of photoconversion from the nonfluorescent to a stable bright-red fluorescent

form (*kindling*). This *kindling fluorescent protein* (KFP1) allows rapid, repeated reversible kindling involving less harmful green light (compared to UV and blue light) and can be used together with other fluorescent markers for FRET analyses or multicolor imaging. For example, when used concurrently with PA-GFP, the distinctive differences in the photoactivation light required for them (blue for PA-GFP and green for KFP1) and their fluorescence products (green and red, respectively) can be used for precise in *vivo* photolabeling to track the movements of cells, organelles, and proteins. KFP1 was already used for *in vivo* cell labeling in mRNA microinjection assays to monitor *Xenopus* embryonic development and to track mitochondrial movement in mammalian cells. Using site-directed mutagenesis also showed that amino acids spatially surrounding Tyr(66) in the chromophore are crucial for kindling, probably involving chromophore-turning or cis–trans isomerization. They have also obtained novel variants that get kindled upon blue-light irradiation. The diversity of photoactivated fluorescent proteins discovered through site-directed mutagenesis is certainly poised for wide applications in the future.

As in photoactivatable fluorescent proteins, photobleaching also allow selected pools of fluorescent proteins to be distinguished from others and be monitored as they reequilibrate, without affecting protein pathways or creating protein gradients. Two techniques are used: the fluorescence recovery after bleaching (FRAP), and the fluorescence loss in photobleaching (FLIP). During FRAP, an area of the cell is photobleached under an intense laser pulse and the movement of unbleached molecules from the neighboring zones into the bleached area is recorded by time-lapse microscopy. FLIP, on the other hand, allows repeated photobleaching fluorescence to be performed in one area of the cell while collecting images of the entire cell. By monitoring the nonphotobleached areas, the movement of fluorescent-tagged proteins can be observed and the continuity of the cellular environments can be studied.

The various GFP-based tools of monitoring kinetics of gene and protein expression described above are summarized in the schematic diagram below (Fig. 4).

3.2 GFP-based FRET for Studies of Protein–Protein Interactions and Signal Activation

Fluorescence resonance energy transfer is the radiationless transfer of excited-state energy from an initially excited donor to an acceptor where the latter reemits light at another wavelength. It depends on the degree of overlap of the emission spectra of the donor and excitation spectra of the acceptor, their distance from each other and the relative orientation of the chromophore's transition dipoles. The efficiency of FRET is inversely proportional to the distance between two chromophores. It is proportional to the inverse sixth power of the intermolecular separation and it takes place only when they are separated by less than 10 nm apart. This means that compatible GFP-tagged proteins undergo FRET only when they are associated with direct binding or as part of protein complex. FRET imaging, therefore, provides spatial information about protein localization at a resolution unparalleled by any optical microscopes. The most commonly used GFP variant pairs for FRET experiments are the CFP (as the donor) and YFP (the acceptor) (Fig. 5). There are various ways to detect

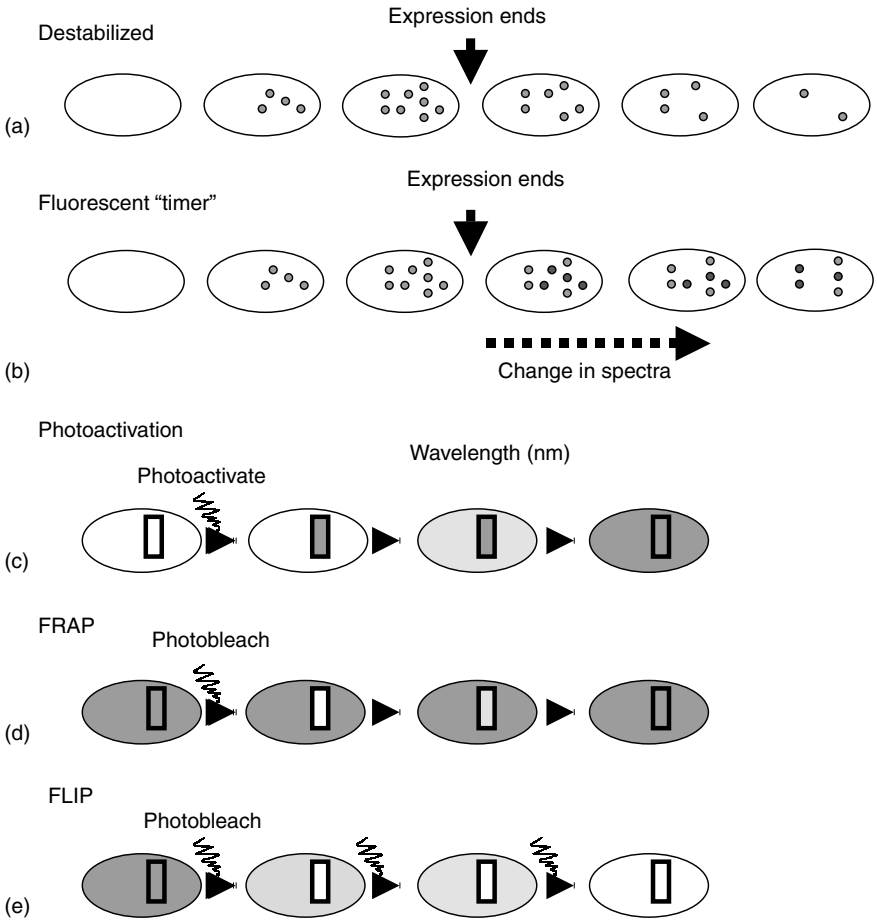

Fig. 4 GFP-based kinetics studies of gene and protein expression. (a) Destabilized fluorescent protein that is degraded as expression ends. (b) Fluorescent *timer* that changes its spectra with time. (c) Photoactivation allows selected irradiation and activation of certain pool of GFP (indicated by rectangle) such that their distribution out of this region can be monitored. (d) In Fluorescence Recovery After Photobleaching (FRAP), the recovery of fluorescent molecules into the region that is preirradiated and photobleached can be assessed to determine diffusion coefficients and mobile fractions. (e) In FLIP, a region of the cell is repeatedly photobleached and that movement of new fluorescent molecules into this region results in loss of fluorescence outside the target area. This helps assess the boundaries of protein's diffusional movement within the cell. Figures (a) and (b) are modified from van Roessel, P., Brand, A.H. (2002) Imaging into the future: visualizing gene expression and protein interactions with fluorescent proteins, *Nat. Cell Biol.* **4**, E15–E20 and figures (c), (d) and (e) are modified from Lippincott-Schwartz, J. and Patterson, G.H. (2003) Development and use of fluorescent protein markers in living cells, *Science*, **300**, 87–91 (see color plate p. xxv).

and measure FRET, which is dependent on the degree of association between two fusion proteins. One can either use the ratiometric method to determine the ratio of acceptor to donor fluorescence, or use the spectral measurement approach where the emission profiles of interacting FRET pair can be interpreted as additive mixture of emission spectra of two component chromophores. The third way is to use fluorescent lifetime imaging microscopy (FLIM) where energy transfer from donor to acceptor results in a decrease in the donor fluorescence lifetime. This method is useful for chromophores that are nearly identical in their emission spectra, and for donors that are prone to photobleaching.

FRET system has also been used between GFP and other chromophores, such as fluorescently labeled antibodies or luciferase. Bioluminescence resonance energy transfer (BRET) has been used in studies of protein complex where excitation illumination is an disadvantage to the sample. Examples for this include use of *Renilla* luciferase with enhanced YFP for protein interactions in circadian clock complex in cyanobacteria.

In addition to studies of protein–protein interactions, several important applications of GFP-based FRET in bioimaging have also been developed. Some of these fluorescent reporters are used as indicators of concentrations of second messengers or activation of certain biological

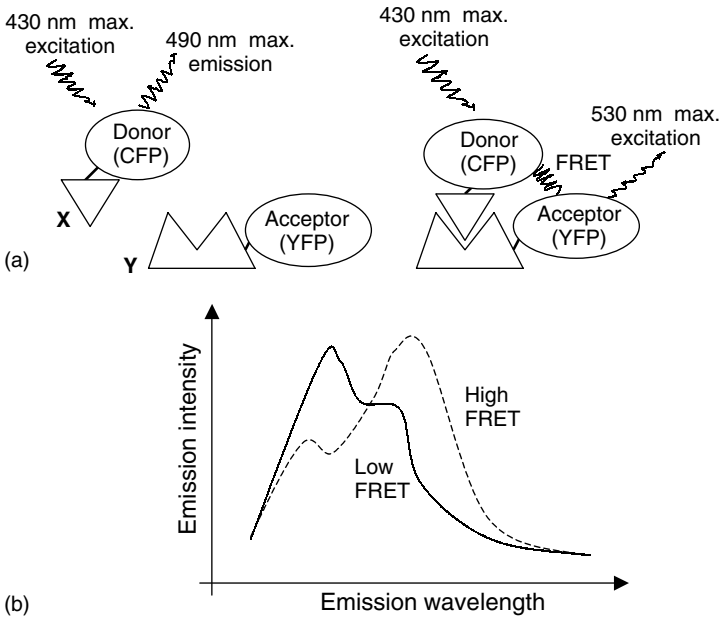

Fig. 5 Principles of fluorescence resonance energy transfer (FRET) with fluorescent proteins. (a) Schematic representation of FRET. (b) Schematic spectra of two fluorescent proteins undergoing FRET. Changes in the spectra reflect the extents of FRET, hence proximity between two interacting partners. Figure is (Adapted from van Roessel, P., Brand, A.H. (2002) Imaging into the future: visualizing gene expression and protein interactions with fluorescent proteins, *Nat. Cell Biol.* **4**, E15–E20.)

pathways. The first sensor for intracellular Ca^{2+} concentration, termed *CAMeleons*, incorporated a calmodulin domain and their ability to change color in the presence of different Ca^{2+} levels. Improved versions of this biosensor have since been reported that saw decreased pH and chloride sensitivity but increased photostability. Beyond ion-sensing, GFP-based FRET are used to examine various downstream signaling targets, including the cAMP, cGMP and the Ras family G-protein activation. To visualize Ras signaling in live cells, a single-gene construct encoding CFP-Ras and the Raf Ras-binding domain (RBD)-YFP was fused with a protein linker domain. After targeting the cell membrane by farnesyl moiety and being activated by the growth factor, RBD binds Ras resulting in a direct readout of Ras-activation patterns. Intriguingly, there was a wave of activation from cell membrane to nucleus – something unexpected based on previous biochemical data. Since the interacting partners were synthesized as a single-construct sensor, the Ras-GFP is very unlikely to have affected endogenous Raf and interfere with its signaling. Spatial and temporal dynamics of other signaling pathways have also been elucidated recently using the same approach. As cells respond to stimuli, certain pathways become activated or inactivated through series of specific protease actions, for example, involvement of caspases in apoptosis. To provide a direct *in vivo* marker for such a cleavage reaction, caspase-3-sensitive DEVD amino acid sequence was placed between BFP and GFP, and FRET was monitored for the caspase activity. One could envisage that by coupling the GFP-based FRET, various activation processes inside the cell can now be more readily monitored and quantified to provide a more dynamic picture of the *in vivo* setting.

3.3 GFP-fusion Protein for Imaging Cell Dynamics, Subcellular Localization, and Cell Signaling

One of the earliest and most exciting applications of GFP is the ability to track the movement of its fusion proteins in the cells *in vivo*. They have been very widely used in various experimental systems including viruses, plants, *Drosophila, Xenopus*, zebrafish, *C. elegans*, mouse, and other mammalian cells. Examples include studies of protein movement in many subcellular compartments or organelles such as targeting of GFP fusion protein domains to signaling metabolites such as phosphoinositides on the membrane. Using the same strategy, the pleckstrin homology (PH) domains of the cytosolic regulator of adenylyl cyclase (CRAC) and the general receptor for phosphoinositides (GRP1) were shown to be localized to the leading edge of the cell moving chemotactically towards a gradient of cyclic AMP. However, while the PH domain of CRAC concentrated solely on the leading edge during the chemotaxis, the GRP1 counterpart appeared to spread more posterior than CRAC. Indeed, various PH domains of varying binding affinity for phosphoinositides are also used as selective sensors for studies of signaling in insulin or growth factors, phagocytosis and macropinocytosis. Likewise, this approach could be used for studies of protein translocation from cytoplasm to nucleus and intracellular trafficking. For example, in signals leading to activation of transcriptional process, it was shown that the GFP-tagged STAT transcriptional factor clearly translocated to nucleus upon stimulation whereas the trafficking of ADP-ribosylation factor was demonstrated to be important for

maintenance of endoplasmic reticulum morphology in the plant *Arabidopsis*.

Cells perform dynamic process where subcellular components are continuously broken down and resynthesized and through local remodeling of cytoskeleton, they could undergo various morphological changes during different stages of growth; for example, cell division, cell migration, endocytosis, phagocytosis, or differentiation. Tagging of actin-binding proteins with GFP revealed detailed process of local synthesis and breakdown of actin cytoskeleton and by varying the ratio of labeled and unlabelled monomers in filaments of microtubule and actin microfilaments, it is now possible to observe them as *beads on a string*. Coupled with the FRET (see Sect. 3.2), the activation states of various small G-proteins of the Ras and Rac family can be monitored where Rac is activated as expected in the leading and trailing edges of the chemotactically moving cells, where active remodeling of the cytoskeleton takes place. Lately, the FLAP system has been employed with CYP and YFP of actin (Fig. 6a) and the dynamics of actin transport has been delineated during cell protrusion at the speed of 5 $\mu m\ s^{-1}$ in a process that is likely to involve active transport rather than diffusion. The dynamics of cell shape changes in response to the effects of a novel apoptosis-inducing Bnip2 and Cdc42GAP Homology (BCH) domain where cell shrinkage follows an earlier protrusion was also recorded. In other closely related proteins, extensive cell elongation was observed with the unique distribution of the protein on the leading edge (Fig. 6b). With the availability of CFP, YFP, and DsRed, triple labeling for more precise studies of subcellular localization of proteins of interest can now be obtained (Fig. 6c).

In addition to imaging of intracellular events, various forms of protein movement between cells *in vivo* or in tissue development have also been recorded using the GFP-fusion system such as those seen during the formation of *Drosophila* wing imaginal discs or during the *Drosophila* dorsal closure. Similarly, movement across synapses between cultured cortical neurons and the formation of dendrites or synapses in developing zebrafish embryos have also been recorded with the use of GFP-based reporter system. Likewise, the order of cell differentiation in developing eye disc of *Drosophila* could be demonstrated by double labeling that incorporated an enhanced mutant of DsRed as a developmental timer (Fig. 6d). In plant cell culture, a secretable form of GFP by addition of signal peptide is also being developed as a reporter for bioprocess applications.

3.4 GFP for Tracing Microbial Gene Expression and Host-pathogen Interactions

GFP are also popular among microbiologists. As for eukaryotes, GFP is used frequently to address the issue of bacterial gene expression and its regulation both at real-time and at single-cell level. An elegant example of transcriptional regulation in bacterial system is shown in flagella biosynthesis and chemotaxis where the expression of 14 flagella operons was monitored in real time using GFP on a low copy plasmid. Each of the 14 strains carried a different promoter-GFP construct and was grown in parallel. Cluster analyses of the fluorescence level detected at regular intervals revealed unexpected findings that the order of class 2 operon expression corresponded to spatial position of

the gene products in the flagella motor complex.

By incorporating fluoroscence-activated cell sorter (FACS), GFP can be employed in high-throughput screening of libraries of cells, for example, those that are expressed preferentially in the host. Similarly, GFP coupled with confocal microscopy allows probing into the structure of biofilms and also various aspects of cell dynamics including cell division, chromosome duplication and segregation, protein localization, and bacterial chemotaxis.

In other cases, the entry of microbes or its sub-particles such as human immunodeficiency virus, bacteria (& Fig. 6e;) or plant viruses to the host cells or tissues were monitored with relatively good resolution and provides important insights on the potential mechanism of pathogenesis. Finally, GFP is also being used as a screening tool during food preparation process. For examples, monitoring the *Lactobacillus sakei* in fermented meat products or the food colonization by *Aspergillus flavus*.

3.5 GFP Imaging of Tumor Growth, Metastasis and Angiogenesis

Unlike *in vitro* cellular system, one of the most difficult hurdles in studies of whole-animal physiology or pathophysiology is the ability to trace with confidence the behavior of cells or tissues and monitor them for a certain period of time. One good example is in the field of tumor biology where following the natural course or impediment of tumor progression and metastasis requires high specificity and high resolution of signal for the markers used. Recently, various groups have tried using GFP system for the purpose and the results are promising. Some have expressed GFP at high levels in cancer cells both *in vivo* and *in vitro* and transplanted them into animals and visualized *in situ* in fresh tissues where they have shown that GFP expression does not affect the metastatic behavior. Others have developed GFP models of metastatic disease for cancers in lung, prostate, melanoma, colon, breast, ovary, and brain. In some models, visualization of tumor growth, angiogenesis, dormancy, dissemination, invasion, and metastasis were made using the quantitative transcutaneous whole-body fluorescence imaging (Fig. 6f). The increased contrast between brightly fluorescent tumor tissue and blood vessels *in vivo* also greatly facilitates testing of antiangiogenic agents during metastatic development. In related work, Ahmed et al. used the mouse mammary virus promoter to directly drive the expression of GFP in the mammary gland for the analyses of transgenic mammary tumors and monitoring metastases *in vivo* at the single cell level of resolution. For clinical applications, selectively targeted tumor cells with retroviral GFP hoping to identify future occurrence of metastasis. Other prospects include labeling tumor-infiltrating lymphocytes and bone marrow that confer chemoresistance for the similar purposes. It might one day become a regular regime to use GFP transgenic rodents as vehicles for antidrug testing.

4 GFP and Transgenic Organisms

The pioneer work of to introduce the *GFP* gene into transgenic *C. elegans* not only demonstrated a new reporter gene in transgenic research but also revolutionized the transgenic field in many aspects. Compared to the traditional reporter genes, such as *chloramphenicol acetyl transferase* (*CAT*), *β-galactosidase*, and *luciferase*, *GFP* allows gene expression to be directly observed in real time in

living embryos/organisms and thus a dynamic event can be recorded. The use of GFP also eliminates the need of sacrifice of living samples for *in vitro* analyses. Despite that GFP is less sensitive than other reporters due to the lack of enzyme amplification effect, generally a single *GFP* transgene is sufficient to produce visible green fluorescence for detection. With the later development of many improved GFP variants and new species of fluorescent protein reporters, both the detection sensitivity and the fluorescent color spectra have been greatly improved.

So far, *GFP* has been used to produce transgenic organisms for many multicellular species, ranging from *C. elegans, Drosophila*, mosquitos, silkworms, sea urchins, ascidan, zebrafish, medaka fish, *Xenopus*, mice, rats, cows, pigs, monkeys to several species of plants. With the rapid progress of *GFP* transgenics, new applications of *GFP* transgenic organisms are constantly explored and reported. Now *GFP* transgenic approach has become a standard assay for characterization of gene regulatory elements for spatial and temporal expression, for analysis of gene expression program *in vivo*, for labeling cells to facilitate many experimental operations, and for formation of fusion proteins to determine the subcellular localization of a target protein and use as a tag to study the function of a target protein. In addition, *GFP* transgenic organisms also have numerous specialized applications, such as mutagenesis and mutant analysis, drug screening, biomonitoring, and ornamental. The following is a brief summary of these applications.

4.1 Analysis of Gene Promoters by Transient Transgenic Assay

In general, there are two types of transgenic systems: one is a transient transgenic assay in which analyses of gene expression are carried out when the introduced foreign gene remains in the extrachromosomal form; the other is a stable transgenic line where the transgene has been stably integrated into the host genome. The transient transgenic assay provides a rapid and convenient way to analyze a gene promoter, which generally contains many distinct binding sites called *cis*-elements that interact with specific proteins factors to control where, when, and how strongly the gene is expressed. By splicing different regions of a promoter to a reporter gene, analysis of its temporal and spatial expression allows a thorough investigation into the activity of a promoter. Compared to other commonly used reporter genes, *GFP* is particularly useful for dissection of *cis*-elements responsible for temporal and spatial patterns of gene expression. For example, have introduced into zebrafish embryos a series of deletions of the zebrafish *GATA-2* promoter ligated to the *GFP* reporter gene and was able to identify three distinct tissue-specific elements that enhance gene expression specifically in blood cell precursors, the enveloping layer of skin epithelia, or the central nervous system. The disadvantage of the *GFP* reporter gene in promoter analysis is the difficulty of quantifying reporter gene activity. This can be partially overcome by counting the number of expressing cells and by arbitrary classification of GFP expression into different intensity groups.

4.2 Recapitulation of Gene Expression Programs in Stable Transgenic Lines

Generation of stable *GFP* transgenic organisms under a tissue-specific promoter has become an established assay to analyze the expression program of a target gene. In

general, the GFP expression pattern faithfully reflects that of the endogenous gene. This approach is particularly powerful for the species with external development, such as invertebrate species, fish and amphibians, as GFP expression can be obtained in real time throughout embryogenesis and development. The zebrafish is probably the best model for this type of studies because of its rapid development as well as its transparent embryos to allow all major organs and tissues to be easily observed. The first stable line of *GFP* transgenic zebrafish under a zebrafish tissue-specific promoter was reported by. In this study, a 5.6-kb erythroid-specific *GATA-1* promoter was linked to the *GFP* reporter gene. Analyses of expression in the transgenic progeny showed that GFP was specifically expressed in erythroid cells from the progenitors to adult red blood cells, similar to the endogenous *GATA-1* expression. Thus, the *GATA-1:GFP* transgenic line provide an excellent model for a real-time study of the development of erythrocyte cell lineage. We have also created a double-color transgenic zebrafish line in which GFP is expressed in skin cells while RFP in muscle cells (Fig. 6(g)).

However, depending on the length and region of the promoters used, sometimes only a subset of cells that express the endogenous gene are able to express transgenic GFP because of the lack of certain gene regulatory elements in the promoters used. In mice, this limitation has been overcome by use of the gene knock-in technology, by which a functional gene like *GFP* is inserted, through embryonic stem cell–mediated homologous recombination, into a target gene locus and thus GFP transcription is completely under the control of the target gene promoter. Therefore, the expression pattern of the endogenous target gene can be fully recapitulated by visible GFP expression. For example, have knocked-in the *GFP* reporter gene into the *GATA-2* gene locus and the knock-in transgenic line faithfully recapitulated the endogenous expression profile of *GATA-2*, displaying green fluorescence widely in various tissues. In contrast, the expression profile in the regular *GFP* transgenic line by random insertion of up to 9-kb *GATA-2* 5′-flanking region linked to the *GFP* cDNA revealed that *GATA-2* expression was only partially recapitulated by transgenic GFP expression. For example, GFP expression in the urogenital tissues and in the aortic endothelial cells was observed in *GFP* knock-in transgenic line but not in the random insertion transgenic line.

Because of tissue-specific GFP expression in transgenic organisms, specific sets of cells are labeled by GFP expression and the development of these cells can be traced from the beginning of GFP expression. This is particularly useful to trace cell lineage, cell migration and axon growth of neurons during development. Another example of using *GFP* transgenic organisms to study cell lineage is use of an inducible promoter. In a *hsp70:GFP* transgenic zebrafish line generated by Halloran et al., the activation of GFP expression can be induced not only by heat shock but also by laser microbeam. Thus, by focusing the laser microbeam on specific cells, cells can be selectively activated for GFP labeling and these cells can then be traced during development.

4.3 Formation of GFP Fusion Proteins

In many cases, GFP can be fused to a complete or partial target protein and the

fusion proteins generally have dual functionality. GFP serves as a visible marker to monitor the cellular localization of target protein. To study cellular structures and dynamics in living cells of multicellular organisms, have carried out a large-scale project on random insertion of *GFP*-cDNA fusions into *Arabidopsis* genome and they were able to identify a variety of cellular localizations. Another potential of GFP fusion protein is to investigate both the expression and function of target protein simultaneously. For example, have generated a *C. elegans* transgenic line to express GFP-Elt (a GATA specific factor) fusion protein under its own gut-specific *Elt* promoter and found that the fusion protein was specifically expressed in gut nuclei and rescued the *elt-2* null mutant.

4.4 Use of GFP as Transgenic Marker and Labeling of Cells by GFP Expression

GFP is also commonly used as an *in vivo* reporter to assess frequency of transient and stable transformation. In plant cells, GFP has been used as a marker for selection of transformed cells to replace antibiotics markers. This also has practical applications to address the concern of using antibiotics resistant genes in field-released genetically modified crops. In mice, using *GFP* transgenic cells in embryonic chimera, GFP expression has been used as a preimplantation screen marker to improve the success rate of transgenic embryos. For transgenesis, *GFP* gene construct can be cointroduced into the transgenic organism and expression of visible GFP can be conveniently used to identify transgenic individuals. For example, in *Xenopus*, it has been proposed to coinject a crystalline promoter driven *GFP* construct with a target gene construct and thus expression of GFP in lens become a convenient marker for screen of transgenic *Xenopus*.

Targeted GFP expression in transgenic organisms also aids many other experimental operations such as cell and nuclear transplantation and microsurgery. Transgenic GFP labeled cells serve as an excellent donor or recipient for cell or nuclear transplantation, as contribution of the GFP expressing cells to the hosts (or a wildtype cell to a *GFP* transgenic host) can be easily identified in the developing embryos. *GFP* transgenic lines had been used to characterize the *eyeless* mutation in medaka in which either the wild-type transgenic fish donated the cells to the mutant host or *vice versa*. Study of the interaction between donor and host cells leads to the conclusion that the *eyeless* functions in a cell-autonomous manner. Recently, by aiming a laser beam at the GFP labeled retinal fiber in the *Shh:GFP* transgenic zebrafish, selectively ablated the tectum to study visuomotor behaviors in larval zebrafish. Likewise, *GFP* transgenic organisms also provide useful information on the dynamics of cells *in vivo*, for example, the elucidation of GFP-labelled synapses being formed by asynchronous process of branch retraction and elimination.

Owing to the ease of monitoring of gene expression, *GFP* transgenic organisms are also ideal systems to test new experimental tools in gene regulation. For example, *GFP* transgenic organisms have been widely used to test the efficiency of RNA interference (RNAi) in almost all model organisms including *C. elegans, Drosophila*, zebrafish, mouse, plants etc. Similarly, GFP transgenic embryos are also used to develop another gene knockdown technology using the morpholino antisense oligonucleotides. In addition, GFP has been frequently used to demonstrate the

functionality of some binary transgenic organisms such as the Cre-loxP recombination system and the GAL4-UAS activator–effector binary transgenic systems.

4.5 Mutant Generation and Characterization in Developmental Analysis

There are two areas that *GFP* transgenic organisms can serve as a valuable tool in mutant studies. First, the transgenic lines with restricted GFP expression in specific tissues/organs can be used for mutagenesis screen as the GFP labeled tissues/organs are readily recognizable. Both genetic and chemical (drug) screens can benefit from *GFP* transgenic lines. In the second area, *GFP* transgenic lines may help to characterize existing mutants after introduction of the *GFP* transgene into relevant mutants through standard breeding. Because of the ability to observe a dynamic GFP expression in living embryos, a high resolution of characterization of mutant can be achieved. For example, when transferred the *GFP* transgene from the gutGFP line into *ntl* (*no tail*) mutant and discovered the presence of the liver rudiment in $ntl^{-/-}$ embryos, though it was previously regarded to be absent from the $ntl^{-/-}$ embryos.

Furthermore, *GFP* transgenic organisms also provide an ideal experimental system to investigate the roles of upstream regulatory genes and signals in regulation of development of specific tissues. For example, in a fast muscle-specific *GFP* transgenic zebrafish line, GFP expression is specifically in fast skeletal muscles but not in slow muscles. By manipulating the Sonic hedgehog signals, GFP expression was inhibited because these GFP-labeled fast muscle cells were differentiated into non-GFP expressing slow muscles. Thus, the direct visualization of GFP labeled cells/tissues greatly facilitates the analysis of molecular events involving in the development of these labeled cells/tissues and to screen upstream molecules affecting their development.

4.6 Cell Sorting for *in vitro* Culture and Cell Type Specific cDNA Library Construction

Tissue-specific GFP expression in transgenic lines is also helpful in purification of rare cell types. These GFP expressing cells can be purified by FACS and used for *in vitro* cell culture and for construction of cell type–specific cDNA libraries, which will be an important source for isolation of transcripts only expressed in a single cell type. This approach is especially desirable if the cells of interest are too limited in number, a successful application of this technique in *GFP* transgenic fish has been reported by Long et al., who constructed a cDNA library using purified *GATA-1*-positive cells from *GATA-1:GFP* transgenic zebrafish embryos and isolated a novel hematopoietic death receptor gene, *ZH-DR*, from this cDNA library. Tomomura et al. have purified the rare cerebellar Purkinje cells from a transgenic mouse line that expresses GFP only in Purkinje cells in an adult brain.

4.7 Development of Transgenic Systems for Biomonitoring

GFP may have another potential applications in biomonitoring of environmental pollution if GFP expression is under control by some inducible promoters such as heavy metals and estrogens. This type

of studies has been carried out in *C. elegans* and fish. Small aquarium fish such as the zebrafish and medaka are particularly interesting for the development of a transgenic system for biomonitoring in which the transgenic fish change to fluorescent colors in the presence of environmental inducers (pollutants). There are many responsible DNA elements that can be considered for addition to the promoter driving the *GFP* reporter gene. Examples include aromatic hydrocarbon responsive elements (AHREs), electrophilic responsive elements (EPREs), metal responsive elements (MREs), estrogen responsive elements (EREs) and retinoic acid responsive elements (RARE, RXRE). These transgenic fish could hopefully be used in the detection of environmental pollutants based on the activated reporter gene expression. Recently, we made a *GFP* transgenic medaka line under the estrogen-responsive vitellogenin promoter and demonstrated that GFP can be turned on by treatment of estrogens. In addition to animals, plants are also being developed to express pH-sensitive derivative of GFP for rapid, environmentally induced changes in cytoplasmic pH in roots.

4.8 Transgenic Ornamentals

The constant discovery of new uses of GFP has now moved beyond science. The vivid fluorescent colors of GFP and other fluorescent proteins prompt us to develop transgenic organisms for ornamental purpose. This is particularly interesting for ornamental fish and flowers. To investigate the feasibility, we have developed several fluorescent transgenic zebrafish lines by using a strong muscle-specific promoter to drive *GFP, RFP*, or *YFP* reporter gene. These transgenic zebrafish can express these fluorescent proteins to a level of 3 to 17% of total muscle proteins and thus the fluorescent colors can be directly observed to unaided eyes even under normal daylight (Fig. 6h).

5 Future of GFP

"Seeing" is believing. When GFP was first introduced about 10 years ago as a marker of gene expression in heterologous host organisms, it gave the whole scientific community an astonishing ride into the internal world of mysterious cellular processes. Its overwhelming acceptance by the scientific community is a testimony for the rapid evolution in the development and improvement on the molecule and its variants as well as the advancement of the technology for its detection and signal interpretations. Today, they do not merely provide a spectacular view of internal structure of cells and lively protein movement within and between cells but also promise to enable more sophisticated studies of protein dynamics such as protein–protein interaction and second messenger cascades during intracellular as well as intercellular signaling.

In the postgenomic era, there is an urgent need to address the issue of gene and protein functions in the context of single cell system as well as the whole animal physiology. With many aspects of applications already described above, GFP can certainly fulfill a significant role in this *functional genomics* endeavor. The key question here is, can we expect another big wave of GFP green revolution? Or, simply, has it reached its full utility? The biggest challenge still lies in two major camps: the hardware and software development for

signal detection, analyses, and interpretation, as well as more refinements towards the biochemical properties of GFP and its variants, including other GFP-like proteins from the Anthozoa animals. While engineers are geared with more advanced imaging systems that are more sensitive with filters for detection of different chromophores and with quicker cameras for image capturing, biologists and chemists too are to place their creativity in tackling some of the limitations of GFP and arrive at more versatile and diverse collection of variants for dynamic bioassays, either by protein engineering or by hunting through nature. In the meanwhile, many of us will likely still be amazed and grateful by the power of GFP.

Keywords

Amixis
Asexual propagation of plants by fragmentation, cuttings from stems, leaves, and roots, by rhizomes or bulbils. Offspring have identical copies of the parental genome.

Amphimixis
Sexual reproduction including formation of haploid gametes and their fusion.

Apomixis
The asexual formation of a seed from the maternal tissues of the ovule, avoiding the processes of meiosis and fertilization.

Auxin Gradients
Differential (graded) distribution of the plant signaling molecule indole-3-acetic acid, IAA, which mediates various patterning processes.

Double Fertilization
Fertilization in angiosperms when one sperm fuses with the egg cell and the second sperm fuses with the two polar nuclei. These two events usually result in the formation of the diploid zygote and the triploid primary endosperm nucleus. Ploidy level of the endosperm is determined by the ploidy level of the fusion nucleus, which depends on the type of embryo sac formation.

Embryogenesis
Process that transforms a single-celled zygote into the embryo comprising all the basic pattern elements of the future plant.

Endosperm
Special tissue in angiosperms originating from the triploid primary endosperm cell. The roles of the endosperm in the embryo development are both nutritive and regulatory. Developmental types of endosperm (nuclear, cellular, helobial) are distinguished by differences in nuclear division and cell wall formation. Endosperm can function as a storage tissue of the mature seed (albuminous seeds) or as nutritive tissue for the developing embryo (exalbuminous seeds).

Female Gamete
Egg cell.

Gametophyte
Haploid generation producing male and/or female gametes that form a zygote upon fertilization.

Incompatibility
Inability of a fertile hermaphrodite flowering plant to produce a zygote after pollination. Various types of the self-incompatibility prevent inbreeding; cross-incompatibility presents a barrier for remote pollination.

Incongruity
Incompleteness of space and time coordination in the plant reproduction process caused by evolutionary divergence.

Male Gamete
Sperm cell.

Seedling
Juvenile form of plant, which consists of a shoot apical meristem, embryonic leaves (cotyledons), hypocotyl, and root with root apical meristem. Seedling is a product of seed germination.

Somatic Embryogenesis
Formation of embryo-like structures originating from somatic cells. Very rarely spontaneous *in planta*, more often induced in plant tissue cultures.

Sporophyte
Diploid generation producing haploid spores.

Zygote
Product of gamete (egg cell and sperm cell) fusion, the first cell of a new sporophyte generation.

Plant reproduction involves both *asexual propagation* (with various types of vegetative reproduction) and *sexual reproduction*. Alternation of haploid and diploid phases is typical for sexual reproduction. Processes leading to the formation of haploid male and female gamete and their subsequent fusion restoring the diploid state are parts of one plant life cycle. Various types of *apomixis* represent modified forms of asexual reproduction by which seeds are produced without fertilization.

1 Asexual (Vegetative) Reproduction – Amixis

Asexual (vegetative) propagation of plants by fragmentation, bulbils, rhizomes, or underground organs like roots and tubers produce offspring that have identical copies of the parental genes. Such propagation allows rapid colonization of a new site and enables even isolated individuals to reproduce. This ability of vegetative plant reproduction is being exploited in horticultural practice for multiplication of desired clones for a long time. Nevertheless, the development of plant tissue cultures amplified the rate of multiplication and extended the list of organs and tissues, in which induction of organogenesis can be initiated. Furthermore, this approach also permitted the development of structures resembling various stages of regular zygotic embryogenesis from somatic cells and/or pollen grains. *SOMATIC EMBRYO RECEPTOR KINASE1* (*SERK1*) is expressed transiently in a small population of embryo competent cells up to the globular stage and seems to be a highly specific signal transduction system of somatic embryogenesis. Most other genes cloned from somatic embryos of carrot (*DC8, DC59, and EMB1*) are homologous to *LATE EMBRYOGENESIS ABUNDANT* (*LEA*) genes. Pollen embryogenesis *in vitro* can be induced by various signals, such as heat-shock treatment or starvation, which can affect organization of cytoskeletal elements and lead to a symmetrical cell division.

2 Sexual Reproduction – Amphimixis

Almost all eukaryotic organisms have evolved a mode of sexual reproduction not only to permit the maintenance of the species but also to increase genetic diversity, which is the basis for adaptation and evolutionary potential. Sexual reproduction is brought about by specialized structures in which the haploid gametes as well as structures and/or mechanisms that ensure the fusion of these gametes are produced. Haploid *male* or *female gametes* are formed in special flower tissues, called *sporangia*, during the processes of *sporogenesis* (formation of haploid spores by meiotic reduction division) and subsequent *gametogenesis* (differentiation of the gametes) (see Sect. 2.3). Somatic chromosome number is restored after gamete fusion – *fertilization* – that results in *zygote* formation. The zygote is the first cell of the next sporophytic generation. Mitotic activity of the zygote and differentiation of these cells leads to *embryo* formation. The mature embryo enclosed within the seed is the structural link between the completed gametophytic generation and the future sporophytic generation of the plant.

2.1 Plant Life Cycle, Alternation of Sporophyte/Gametophyte Generations in Plant Evolution

The eukaryotic life cycle includes events leading to the formation of gametes as well as the development ensuring their fusion. Two alternating generations can be recognized in the plant life cycle: a haploid phase, known as the *gametophytic* and a diploid phase, known as the *sporophytic generation*. The gametophyte reproduces by means of *gametes*, but it does not reproduce itself directly. Instead, the zygote resulting after gamete fusion develops into the sporophyte. The

sporophyte, similarly, is not reproduced directly, but forms reproductive cells known as *spores*, which develop into gametophytes. Thus, the gametophytic and the sporophytic generations alternate and reproduce each other. The relative lengths of the sporophyte and the gametophyte generations have changed during evolution from a dominant autotrophic (self-feeding) gametophyte and a nutritionally dependent sporophyte to a dependent gametophyte and a dominant autotrophic sporophyte. In mosses (Fig. 1a), both the embryo and the mature sporophyte are dependent on the photosynthetic gametophyte for nutrition. Meiosis within the capsule of the sporophyte yields haploid spores that are released and germinate to form a male or female green gametophyte. Differentiation of the gametophyte produces *antheridia* with sperm cells in males and *archegonia* with eggs in females. Fertilization occurs after transfer of sperm cells in drops of water, and the sporophyte generation develops in the sporangium that remains attached to the gametophyte. Both the gametophyte and the sporophyte of ferns (Fig. 1b) photosynthesize and are thus autotrophic; the shift to a dominant sporophyte generation is apparent. Further reduction of the gametophyte generation during evolution led to the highly reduced gametophyte of angiosperms (Fig. 1c and Sect. 2.3), where the *male gametophyte* is represented only by the *pollen grain* consisting of the *vegetative cell* that develops a pollen tube and the *generative cell*, which produces *male gametes* – the *sperm cells*. The *female gametophyte* of angiosperms is represented by the *embryo sac*, which often contains eight haploid cells, the most important of which is the *female gamete* – the *egg cell* (EC).

2.2 Structure and Development of Plant Sexual Organs

Molecular mechanisms of flower development have recently been extensively investigated in the model plant *Arabidopsis thaliana*. Although other model plants have been used to study the molecular genetics of flower development (e.g. *Petunia* and *Antirrhinum*), this brief overview will focus on recent models of flower development in *Arabidopsis*.

During vegetative growth, the aerial portion of the vegetative plant organs (*shoot*) is a product of the *shoot apical meristem* (SAM). In indeterminate species (like *Arabidopsis* and similar plants with raceme inflorescence), flowers are formed in *inflorescence*, growing out from the rosette of pedestrian leaves in *Arabidopsis*. Thus, induction of flowering in *Arabidopsis* involves two transitions: (1) formation of inflorescence (otherwise known as *bolting*) from *inflorescence apical meristem* and (2) formation of individual flowers from *floral meristems* growing out from the inflorescence. In determinate species, the inflorescence meristem differentiates into a single floral meristem leading to formation of a single terminal flower.

Multiple endogenous and environmental stimuli lead to the switch from vegetative to reproductive growth (see the following). After bolting is induced, secondary inflorescence meristems, *axillary meristems*, are formed giving rise to lateral inflorescences (coflorescences) on the axils of 2 to 5 *cauline leaves*. It is still not completely clear whether SAM directly switches to the inflorescence apical meristem or whether there is some interphase between the vegetative and reproductive phases. The first model predicts that cauline leaves and the axillary meristems are produced from

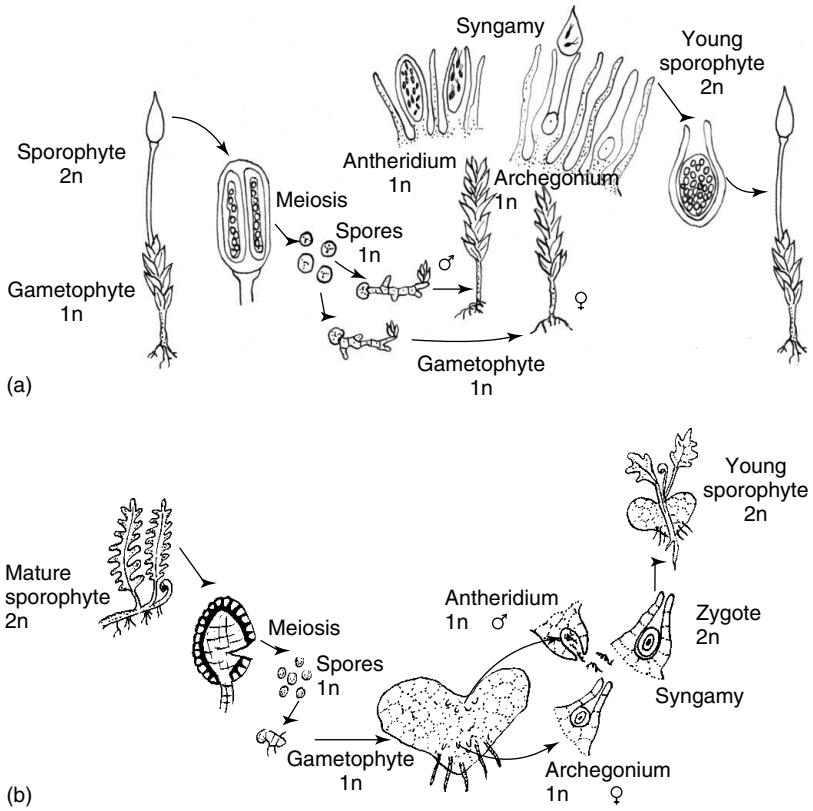

Fig. 1 Schematic representation of the alternation of sporophyte/gametophyte generations in plant evolution. (a) Life cycle in mosses: the sporophyte generation in mosses is reduced to only a sporangium within which haploid spores are formed during meiosis. Germinating spores form a male or female green gametophyte. Differentiation of the gametophyte produces antheridia with sperm cells in males and archegonia with eggs in females. Fertilization occurs after transfer of the sperm cell in a drop of water to the egg cell within the archegonium. The next sporophyte generation develops in the archegonium and remains attached to the gametophyte. (b) Life cycle in a fern: most (but not all) ferns are homosporous and produce only one type of spore within a structure called the *sporangium*. The gametophyte develops from the spores and can produce both male and female sex organs. Water facilitates fertilization like in mosses. The biggest contrast between the mosses and the ferns is that both the gametophyte and the sporophyte of the fern are autotrophic (According to Fosket, D.E. (1994) *Plant Growth and Development: A Molecular Approach*, Academic Press, San Diego, CA). (c) Life cycle in the angiosperms: the gametophyte generation of the angiosperms is reduced to just a few cells. The male gametophyte is formed after meiosis in microsporangia located in anthers and is represented by the pollen grains, which are complexes of two or three cells. The female gametophyte – the embryo sac – containing the egg cell, synergids, antipodals, and the central cell, is formed within the megasporangium (ovule). Angiosperm fertilization no longer relies on water like, in mosses or ferns. Production of a seed coat, which forms a layer of protection around the embryo, and a further protective layer, the fruit, are unique features of angiosperms. PMCs, pollen mother cells, MMC, megaspore mother cell.

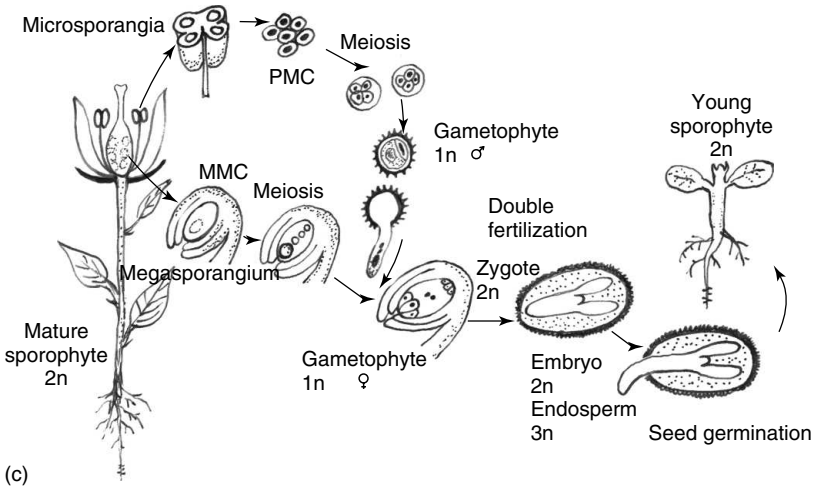

(c)

Fig. 1 (*Continued*)

the inflorescence apical meristem simultaneously with the first floral meristems. The later one proposes that cauline leaves and the axillary meristems are products of the ''interphase'' apical meristem. Recent evidence suggests that both genetic and environmental factors control the process and favor the latter possibility under normal conditions, suggesting the existence of coflorescence-producing *inflorescence interphase* (I phase) between the *vegetative*, leaf-producing *phase* (V phase) and the *reproductive*, flower-producing *phase* (F phase). According to this model, not two but three developmental switches would occur during flowering induction in *Arabidopsis*.

Induction of flowering is controlled by *flowering time genes*, which control the activity of *meristem identity genes*. There are two subclasses of the meristem identity genes in *Arabidopsis*: *shoot meristem identity genes* and *floral meristem identity genes*. The activity of shoot meristem identity genes (e.g. *TERMINAL FLOWER1* (*TFL1*)) specifies the inflorescence apical meristem as indeterminate and nonfloral. The second subclass, floral meristem identity genes (e.g. *LEAFY* (*LFY*) and *APETALA1* (*AP1*)), mediate transformation of the lateral ends of the inflorescence apical meristem into floral meristems, where *floral organ identity genes* are activated (Fig. 2). The floral organ identity genes promote differentiation of floral organ primordia and induce formation of floral organs by activation of organ building genes. Floral organs in *Arabidopsis* (i.e. *sepals*, *petals*, *stamens*, and *pistil*) are organized in four concentric whorls (see Fig. 3). Formation of different organs in each of the whorls reflects interactions of spatially specific gene activities according to the so-called *ABCE model* (Fig. 4) as described below (Sect. 2.2.4.1).

Developmental processes leading to flower formation could be divided into four basic steps occurring in a temporal sequence: (1) switch from vegetative to reproductive growth leading to inflorescence meristem formation, (2) floral meristem identity acquisition by activation of floral meristem identity genes, (3) activation of floral organ identity genes, and finally, (4) activation of flower ''organ building'' genes. Molecular control of all of these

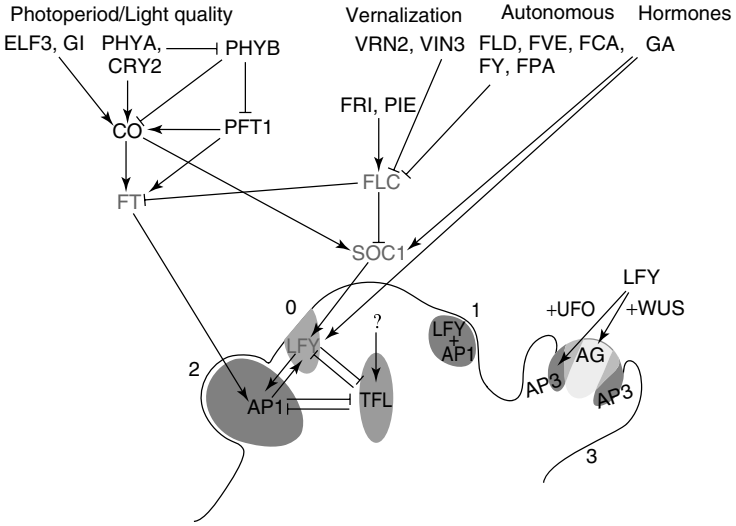

Fig. 2 Schematic representation of gene interactions during flower development in *Arabidopsis*. Selected genes acting in four major pathways of flowering induction and their interactions are shown. Both direct and indirect as well as positive (arrows) and negative interactions are marked; floral pathway integrators are in red. PHYA and CRY2 have similar effects on flowering, but they act via independent pathways. However, for the sake of simplicity, they are depicted as sharing the same one. The colored areas in the schematically depicted inflorescence apical meristem represent approximate areas of the respective gene activities (expression patterns): *AP1* (red), *LFY* (blue), *TFL* (green), *AP3* (brown), *AG* (yellow). *LFY* is first activated in the so-called floral anlagen (floral stage 0) and it precedes the expression of *AP1*. Later on, the expression patterns of *AP1* and *LFY* are overlaid (stages 1 and 2). On the left-hand side, developing floral meristem (stage 2) is shown, on the right-hand side, there are developing flowers at stages 1 and 3. Numbers label the individual stages of flower development (0–3). Overlapping activities of B and C gene classes *AP3* and *AG*, respectively, in the whorl 3 are schematically shown (light brown). At that stage of flower development, expression patterns of *UFO* and *AP3* are similar; *LFY* is expressed all over the developing flower at stage 3 (not shown). *AP1* is expressed all over the flower meristem at stages 1 till early stage 3 and after *AG* induction at stage 3, *AP1* expression is repressed in *AG* domain (whorls 3 and 4), but persist in whorls 1 and 2 (not shown) (See color plate p. xxiii).

processes integrates outputs of many signaling pathways.

2.2.1 Transition from Vegetative to Reproductive Growth

The switch from vegetative to reproductive growth is regulated by flowering time genes via four major signaling pathways: *long-day photoperiod/light quality* and *vernalization pathways*, which mediate the influence of environmental factors and the intrinsic *autonomous* and *hormone-dependent pathways*.

2.2.1.1 Long-day period and light quality.

Arabidopsis is a facultative long-day period flowering plant, which means that *Arabidopsis* comes into flower more rapidly

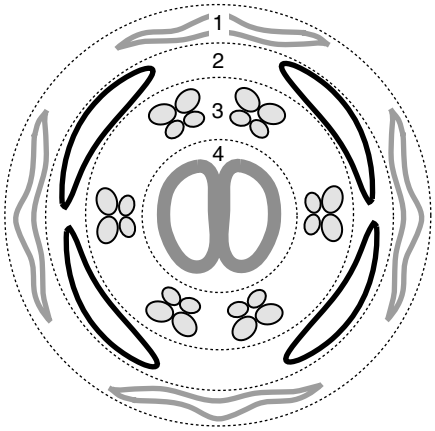

Fig. 3 Scheme of the Arabidopsis flower. *Arabidopsis* flower organs are organized in four concentric whorls. Whorl 1 contains four *sepals*, whorl 2 four *petals*, whorl 3 six *stamens* (four medial and two lateral), and whorl 4 two fused *carpels*, which form the female reproductive organ, the *gynoecium* (pistil).

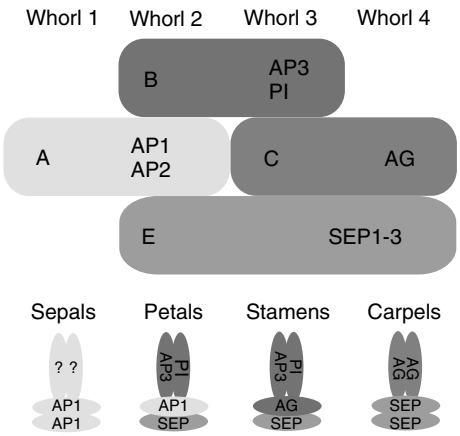

Fig. 4 ABCE model: the overlapping spatial specificity of individual gene classes in the flower whorls 1–4 in *Arabidopsis* is depicted. In the lower part, there are putative complexes of the flower organ identity genes, whose interactions are supposed to be involved in the acquisition of floral organ identity according to the quartet model (According to Jack, T. (2004) Molecular and genetic mechanisms of floral control, *Plant Cell* **16**(Suppl.), S1–S17).

when the light period reaches 14 to 16 h. However, even under short day conditions (light 8–10 h), flowering is induced, suggesting the existence of flowering promotion pathways that are independent of the length of the day period (see the following). Molecules involved in the perception of the day length are light receptors (e.g. *PHYTOCHROME A* (PHYA) and *CRYPTOCHROME2* (CRY2)), and components of the circadian clock (e.g. *GIGANTEA* (GI) and *EARLY FLOWERING3* (ELF3)). Both of these groups of molecules cooperate by the detection of the day length period and the information is transmitted via cyclic expression of *CONSTANS* (*CO*), encoding a putative component of a transcription activation complex that regulates the activity of downstream target genes.

Apart from day length, quality of light also influences initiation of flowering. Under shading, a series of responses known as ''shade-avoidance syndrome,'' including stem elongation and accelerated flowering can be observed. In crowded plant populations, the light is depleted in red wavelengths by chlorophyll of neighboring plants and consequently the ratio of red to far-red light is reduced. In general, red light represses flowering in

Arabidopsis, whereas far-red light has a flowering promotion effect. The change in light quality is perceived by red/far-red receptors, so-called phytochromes. PHYTOCHROME B (PHYB) acts predominantly in red-light perception and mediates inhibition of flowering via repression of *PHYTOCHROME AND FLOWERING TIME1* (*PFT1*), encoding a nuclear protein and putative transcriptional factor (see also Sect. Integration of flowering promotion signals). PFT1 might promote flowering by indirect activation of both *CO* and *FLOWERING LOCUS T* (*FT*, see Fig. 2). PHYA acts primarily in perception of far-red light and together with the blue/ultraviolet A light receptor CRY2, activates flowering. Both PHYA and CRY2 repress *PHYB* and activate *CO* via independent pathways.

2.2.1.2 **Vernalization.** Vernalization, that is, extended cold treatment, mimics wintering under natural conditions and induces flowering in most of the *Arabidopsis* accessions in a quantitative manner. It was found that vernalization leads to changes in chromatin structure or DNA methylation state and subsequent transcriptional inactivation of one of the major floral pathway integrators *FLOWERING LOCUS C* (*FLC*, see the following). After cold treatment, *FLC* repression persists even at subsequent higher growing temperatures. This ''memory of vernalization'' involves the participation of VERNALIZATION2 (VRN2), a putative Polycomb-group protein. Another molecule necessary for the negative regulation of *FLC* by vernalization is VERNALIZATION-INSENSITIVE3 (VIN3), a plant homeodomain protein, which seems to be involved in the measurement of the cold period.

2.2.1.3 **Autonomous flowering promotion pathway.** The autonomous pathway controls flowering time independently of environmental factors, that is, vernalization and photoperiod/light quality. The central role in the integration of different flowering promotion pathways (see the following) is played by *FLC*. *FLC* encodes a MADS-box transcription factor (for more details on MADS-box proteins see Sect. Acquisition of Floral Organ Identity) and the level of *FLC* product is negatively correlated with the time of the flowering induction. Members of the autonomous pathway induce flowering by repression of *FLC*. *FLOWERING LOCUS D* (*FLD*) encodes a protein similar to the component of human histone deacetylase complex and it is supposed to act in the transcriptional control of *FLC* by histone H4 deacetylation. Another member of the autonomous pathway is FVE, a putative retinoblastoma-associated protein, and like FLD regulates *FLC* activity by histone H4 deacetylation. FCA, a protein with two RNA binding domains and a protein binding domain is supposed to interact with FY, a protein with similarity to yeast RNA processing proteins. FCA/FY complex might be involved in posttranscriptional repression of *FLC*. Similarly, *FPA*, another gene with a negative effect on the accumulation of FLC, encodes an RNA binding protein. However, the role of RNA processing in the regulation of *FLC* remains unclear.

2.2.1.4 **Plant hormones.** The plant hormone *gibberellic acid* (GA) promotes flowering in *Arabidopsis* under short day conditions. In the absence of GA, *Arabidopsis* is an obligate long-day flowering plant. Genes involved in the biosynthesis (e.g. *GA REQUIRING1* (*GA1*)) and perception of GA (e.g. *FLOWERING PROMOTIVE FACTOR* (*FPF1*)) are known to be involved

in the gibberellin-dependent regulation of flowering time in *Arabidopsis*. *Abscisic acid* (ABA), another plant hormone, plays a role opposite to that of GA in flowering promotion, that is, it delays flowering. Mutants with lowered biosynthesis of abscisic acid and mutants in genes involved in abscisic acid signaling (e.g. *ABA INSENSITIVE1* (*ABI1*) and *ABI2*) flower earlier under noninductive conditions. Other plant hormones (e.g. cytokinins and ethylene) are also implicated in the regulation of flowering induction; however, the molecular mechanism of their action in flowering induction and interaction with other flowering promoting factors is largely unclear.

2.2.1.5 **Integration of flowering promotion signals.** All of the above-mentioned signals are integrated in a complex network (Fig. 2), leading to the final regulation of downstream targets, the meristem identity genes (e.g. *LFY, AP1, TFL1*). There is quite a small group of factors in *Arabidopsis*, integrating multiple pathway outputs, so-called *floral pathway integrators* (e.g. *FLC*, *SUPPRESSOR OF OVEREXPRESSION OF CONSTANS1* (*SOC1*), *FT* and *LFY*, see above and Fig. 2). *LFY* plays a special role as one of the flower pathway integrators and together with *AP1* belongs to the floral meristem identity genes (see below). *FLC* integrates outputs mediated by both flowering repressing factors (e.g. *FRIGIDA* (*FRI*), *PHOTOPERIOD INDEPENDENT EARLY FLOWERING1* (*PIE1*)) as well as flowering promoting factors (e.g. *FLD*, *FCA*, see above and Fig. 2). *Arabidopsis* accessions with functional *FRI* allele over winter in the vegetative state and after vernalization they flower in spring. Allelic variations found in *FRI* correspond to the variations in flowering time found among different accessions of *Arabidopsis*. *FRI* encodes a protein, which is suggested to be involved in the interactions with DNA or other proteins and FRI inhibits flowering by upregulating *FLC*. This effect cannot be overcome even by the strong flowering promoting effect of a long-day photoperiod. PIE1, a protein with similarity to ATP-dependent chromatin remodeling proteins, also delays flowering by positive regulation of *FLC*. *SOC1*, encoding a MADS-box protein and a flowering activator, is directly repressed by FLC via a MADS binding sequence in the *SOC1* promoter. *SOC1* is also activated by CO and gibberellic acid. The antagonistic effects of FLC and CO on *SOC1* are mediated by the same 351-bp promoter sequence of *SOC1*. *LFY* integrates the outputs from long-day period and GA pathways by separated *LFY* promoter elements. The effects of long-day period on *LFY* might be mediated by SOC1 or another MADS-box protein, AGAMOUS-LIKE24 (AGL24). GA might influence *LFY* via activation of *AtMYB33*, encoding an MYB-like transcription factor that binds to the 8-bp sequence identified in the *LFY* promoter. Finally, *FT* integrates positive control from the long-day photoperiod pathway mediated by *CO* and negative control from multiple pathways integrated by *FLC*. The inhibition of flowering under shading by the PHYB pathway mentioned in Sect. 2.2.1.1 is also integrated by *FT*, as PHYB downregulates *FT* via repression of *PFT1*, encoding a nuclear activator of *FT* expression. Expression of *FT* could also be affected by GA; that process might be repressed by EARLY BOLTING IN SHORT DAYS (EBS), a protein suggested to be involved in chromatin remodeling. For a scheme summarizing the above-mentioned interactions, see Fig. 2.

2.2.2 **Floral Meristem Identity Acquisition**

The final downstream targets of the above-mentioned interactions of flowering

time genes are *LFY* and *AP1*, the floral meristem identity genes. The regulation of *TFL1*, a member of the shoot meristem identity group of genes, is still unclear. *LFY* and *AP1* are necessary to specify a meristem as floral, but they do not act independently of each other. *LFY* directly activates *AP1* and *AP1* is necessary for the function of *LFY* in floral promotion. There is a mutual repression between *LFY* and *AP1* on one hand and *TFL1* on the other. This is consistent with the apparently opposite role of both groups of the genes. *TFL1* maintains the shoot meristem indeterminate and nonfloral and negatively regulates flowering, whereas *LFY1* and *AP1* promote the formation of floral meristem and flowering. LFY1 and AP1 are transcription factors, which might directly regulate *TFL1*. TFL1 is similar to FT (see above), but the molecular mechanism of their opposite functions is unclear.

2.2.3 Flower Formation

2.2.3.1 Acquisition of floral organ identity. Individual flowers are formed by floral meristems growing out from the lateral parts of the inflorescence meristem. Once flower meristem identity is acquired, the prerequisite for proper flower development is spatially delimited expression of flower organ identity genes. This finding led to the postulation of the so-called *ABCE model*, which explains the proper formation of *Arabidopsis* floral organs as a result of interactions among ABCE gene classes (see Fig. 4). *Arabidopsis* floral organs are organized in four concentric whorls. There are four sepals in the most outer whorl 1, four petals in whorl 2, six stamens (four longer medial and two shorter lateral) in whorl 3 and two carpels in whorl 4; the two carpels fuse to form a bilaterally symmetrical gynoecium (pistil, see Fig. 3). The ABCE model postulates that activity of class A genes alone specifies sepals in a flower whorl 1, A + B specifies petals in whorl 2, B + C specifies stamens in whorl 3 and C alone specifies carpels in whorl 4. Genes of class E were additionally found to be necessary for the proper identity of petals, stamens, and carpels (see Fig. 4). Function of ABC genes is specific to the flower meristem; however, in combination with class E genes, they are able to transform even vegetative organs (e.g. leaves) into floral organ-like structures. With the exception of APETALA2 (AP2), a member of a small plant-specific family of transcription factors, products of ABCE genes (see Table 1) are MADS-transcription factors. The MADS-transcription factors are analogs of animal homeotic genes, which, instead of homeodomain, contain the so-called *MADS-box*, found in MCM1 (yeast), AGAMOUS (*Arabidopsis*), DEFICIENS (*Antirrhinum*), and SERUM RESPONSIBLE FACTOR (SRF, human). Additionally, there are D-class genes [e.g. *SEEDSTICK* (*STK*), *SHATTERPROOF1* (*SHP1*), and *SHP2*], which are important for specification of ovule organ identity (see Sect. Ovule identity).

2.2.3.2 Activation of floral organ identity genes. The major activators of floral organ identity genes are *LFY* and *AP1*. As mentioned earlier, *LFY* and *AP1* are flower meristem identity genes, which are necessary for flower meristem identity acquisition. In combination with other factors, LFY and AP1 also act as activators of the flower meristem identity genes *AGAMOUS* (*AG*, C class) and *APETALA3* (*AP3*, B class). LFY and UNUSUAL FLOWER ORGANS (UFO) coactivate *AP3*: LFY is able directly to bind to the *AP3* promoter *in vitro*; UFO is an F-box

Tab. 1 Genes involved in the Arabidopsis flower development.

Gene group	*Gene subgroup*	*Function*	*Selected members of the subgroup*
Flowering Time Genes	Long-day period/light quality pathway	Regulation of flowering by day period and light quality	*PHYA*, *PHYB*, *CRY2*, *GI*, *ELF3*, *CO*, *PFT1*
	Vernalization pathway	Induction of flowering by cold	*VRN2, VIN3*
	Autonomous pathway	Induction of flowering independent of environmental conditions	*FCA, FY, FLD, FVE, FPA*
	Hormone-dependent pathway	Gibberellic acid and abscisic acid dependent regulation of flowering	*GA1, FPF1, AtMYB33, EBS, ABI1, ABI2*
	Floral pathway integrators	Integration of outputs from various flowering time regulation pathways	*FLC, SOC1, FT, LFY*
Meristem Identity Genes	Shoot meristem identity genes	Specification of the inflorescence apical meristem as indeterminate and nonfloral	*TFL1*
	Flower meristem identity genes	Specification of the meristem as floral	*LFY, AP1*
Floral Organ Identity Genes	A	Specification of sepals in whorl 1, repression of class C genes in whorls 1 and 2	*AP1, AP2*
	B	Together with A, specification of petals in whorl 2	*AP3, PI*
	C	Together with class B genes, specification of stamens in whorl 3, repression of A class genes in whorls 3 and 4 and specification of carpels in whorl 4; repression of meristem proliferation	*AG*
	D	Specification of ovule organ identity	*STK, SHP1, SHP2*
	E	Cooperation with ABC genes in specification of petals, stamens, and carpels in whorls 2–4, development of sepals	*SEP1-4*

protein and it functions as a part of the SKP1-cullin-F-box (SCF) complex that targets proteins for ubiquitin-mediated degradation. A recent model suggests a role for UFO in the degradation of the putative *AP3* repressor in whorls 2 and 3 (see Fig. 4). Proper function of B-class genes in petal formation is also dependent on *AP1*, probably via AP1 activation of *UFO* by promoting *UFO* mRNA accumulation at the base of petals in whorl 2 late during flower development (stage 5, see Sect. 2.2.3.4). The central role of LFY in the activation of floral organ identity genes is further supported by its role in coactivation of class C gene *AG*. Together with the homeodomain protein WUSCHEL (WUS), LFY binds to the regulatory region of *AG* in its second intron. The expression of *WUS* in precursor cells of whorls 3 and 4 seems to be responsible for spatial specificity of the LFY/WUS-mediated *AG* activation (see Fig. 4). After *AG* is activated by LFY/WUS, AG in turn represses *WUS* in whorls 3 and 4. WUS promotes the proliferative state of meristem cells and absence of the feedback in *ag* mutants leads to the indeterminate flower phenotype.

2.2.3.3 **Interactions among ABCE genes.** There are two major types of interactions among ABCE genes during flower formation. First, they cooperate in the specification of precursor cells to form individual flower organs as mentioned in previous sections. Second, after initial activation of the floral organ identity genes, the fine tuning of their expressional patterns is achieved by mutual repressive interactions between A- and C-class genes; the territorial competition is also called *cadasteral activity*. The molecular nature of those two types of interactions will be briefly described in following sections.

Multifactorial MADS-box Protein Complexes The vast majority of ABCE genes encode type II MADS-box proteins. Besides an N-terminal MADS-box, a domain with DNA binding, nuclear targeting, and dimerization functions, there are two additional conserved domains in most of the ABCE proteins: a K-domain, responsible for protein–protein interactions and a C-domain, involved in transcriptional activation. The recent *quartet model* suggests formation of tetramers, composed of two pairs of MADS-box proteins, homo- or heterodimers, each of which binds to a single MADS binding site. There are two possible models, explaining the molecular mechanisms of functionality of those complexes. One suggests synergistic effects of individual subunits on the affinity of the entire complex to individual MADS binding sites, the other considers functional complementation of MADS proteins lacking transcription activating domains (e.g. AP3) by the transcription activating domain of interacting partner(s) (e.g. AP1). The quartet model implies formation of tetramers consisting of AP3/PISTILLATA (PI) and SEPALLATA (SEP)/AP1 heterodimers in petals whorl 2 (there are four members of the *SEP* gene family in *Arabidopsis*, SEP1-4), AP3/PI and SEP/AG heterodimers in stamens whorl 3 and AG/AG and SEP/SEP homodimers in whorl 4 (see Fig. 4). Whether AP1 alone (possibly as a homotetramer) or in combination with any other product of a class A gene is responsible for sepal specification in whorl 1 remains unclear. Similar interactions among floral organ identity genes were found in *Petunia* and *Antirrhinum*. It could suggest that the above-mentioned principles might be a unifying dogma of flower organ development, with some species-specific modifications, for example, only class B

and C genes were identified in *Antirrhinum*. However, it should be noted here that the *in planta* nature of MADS–protein complexes remains to be characterized.

Cadasteral activity of A and C genes *AP1* and *AP2* are the earliest class A genes expressed in the floral meristem. *AP1* is expressed throughout the meristem to specify the meristem as floral. Later on (stage 3), the expression of the class C gene *AG* is activated by LFY and WUS (see Sect. 2.2.3.2) in whorls 3 and 4, where the expression of *AG* suppresses transcription of *AP1*. Vice versa, *AP2*, another class A gene, inhibits expression of *AG* in whorls 1 and 2. Interestingly, in the case of *AP2*, posttranscriptional regulation via microRNA (miRNA) leads to the localization of AP2 protein to whorls 1 and 2 (*AP2* mRNA is detectable throughout the flower). Besides class A genes, there are also other, non-MADS genes, working as repressors of *AG* (e.g. *CURLY LEAF* (*CLF*), encoding a homolog of the *Drosophila* Polycomb-group protein *Enhancer of Zeste*, *LEUNIG* (*LUG*), which encodes protein with multiple WD-repeats, *SEUSS* (*SEU*), encoding a protein with a glycine-rich domain and showing similarity to animal LIM domain binding coregulators, *STERILE APETALA* (*SAP*) and *AINTEGUMENTA* (*ANT*), encoding DNA binding protein related to AP2, see also Sect. Ovule patterning). Like *AP2*, *LUG*, *SEU*, and *ANT* repress *AG* in whorls 1 and 2.

2.2.3.4 **Development of floral organs.** Development of the *Arabidopsis* flower was classified into 12 stages, based on the successive appearance of individual landmarks. Stages 1 to 3 are schematically depicted in Fig. 2. Flower development starts when a flower buttress arises (stage 1) and proceeds to the next stage when the floral buttress is separated by grooves (stage 2). In stage 3, sepal primordia arise that overlie the primordium at stage 4. During stage 5, the petal and stamen primordia become apparent and are enclosed by the sepals at stage 6. During stage 6, the gynoecium starts growth as an open-ended tube. At stage 7, primordia of middle stamens become constricted toward their base, thus defining the future stamen stalks (filaments) and develop locules (stage 8). At stage 9, petal primordia become stalked and all organs undergo rapid elongation. When the petals reach the length of lateral stamens, stage 10 begins. Papillae of stigma appear at stage 11 and the stage 12 starts when petals reach the height of medial stamens. Stage 12 ends with the opening of the flower.

Recently, the molecular factors regulating floral organ development have been identified using expressional studies and mutant analysis. Expression of *TAP1* and *FILAMENTOUS FLOWER1* (*FIL1*) encoding a secreted protein and a candidate cell wall protein respectively were identified in anthers of *Antirrhinum*. In *Arabidopsis*, *NAC-LIKE ACTIVATED BY AP3/PI* (*NAP*) represents the downstream target of B-class genes in petals and stamens. *SHOOT MERISTEMLESS* (*STM*), *CUP-SHAPED COTYLEDONS* (*CUC1*), and *CUC2* are expressed in the so-called medial domain, located at the interface of the fused lateral carpel margins in the pistil. These genes are supposed to be important for maintaining the meristematic state of the medial domain, where later on the *placenta* tissue differentiates and from which the ovule primordia arise. *CRABS CLAW* (*CRC*), *SPATULA* (*SPT*), and *TOUSLED* (*TSL*), (see also Sect. Integument initiation and growth) are expressed in the medial domain of

the pistil and might affect the production of ovules.

2.3 Structure and Formation of Male and Female Gametes

In higher plants, male and female gametes, the *sperm* and *egg cells*, are formed in special flower tissues, so-called sporangia. *Microsporangia*, located in *anthers* (Fig. 5), produce a large number of *microspores* that differentiate into mature *male gametophytes* (*microgametophytes*), the *pollen grains*. *Megasporangia*, so-called *ovules*, are located in the ovary of the pistil (gynoecium). In contrast to microsporangia, during megasporogenesis in a majority of plant species, only one of four megaspores differentiates into a functional *megaspore* that develops into a *female gametophyte* (*megagametophyte*), the *embryo sac*. Two *sperm cells* develop from each pollen grain, whereas there is only one *egg cell* in each embryo sac. Both micro- and megagametophytes (i.e. pollen grains and embryo sacs) are multicellular structures that undergo specific developmental processes.

2.3.1 Male Gamete Formation

2.3.1.1 Microsporogenesis.

Archesporial cell number and differentiation The formation of pollen in *A. thaliana* is schematically shown in Fig. 5. In each of four developing locules (microsporangia) formed in the anther, one *archesporial cell* differentiates. The archesporial cell is specified from one of the subepidermal cells originating

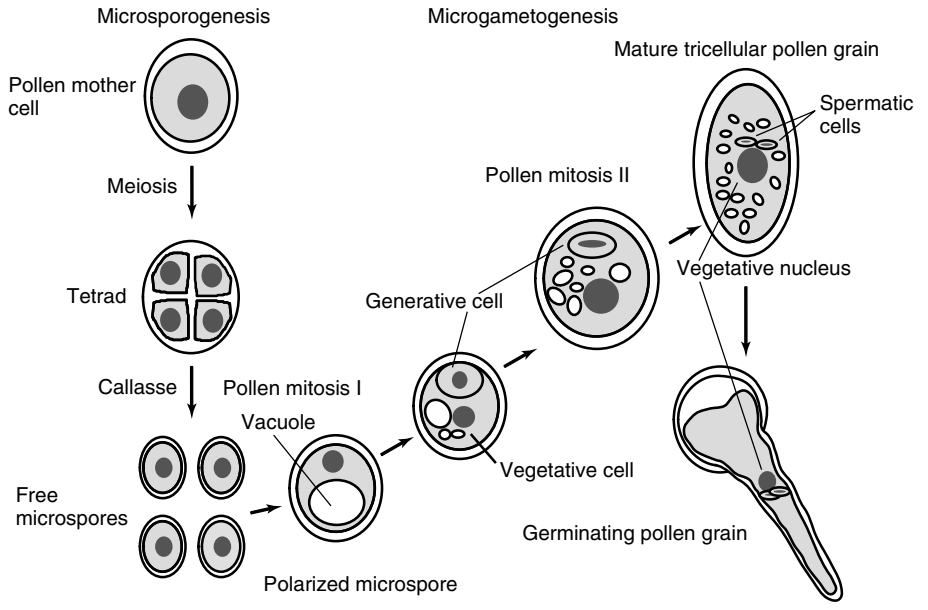

Fig. 5 Male gametophyte development: formation of mature pollen grain from pollen mother cell in *Arabidopsis* is schematically depicted. Cytoplasm is in yellow, nuclei are in red, and vacuoles are in white. For details see text (Sect. 2.3.1). (See color plate p. xxvii).

from the L2 layer. In *Arabidopsis NOZZLE/SPOROCYTELESS* (*NZZ/SPL*) encodes a putative transcription factor similar to MADS-box proteins, necessary for the specification of archesporial cell. *NZZ/SPL* was recently shown to be under direct control of AG (see also Sect. 2.2.3.2). The number of archesporial cells in *Arabidopsis* seems to be determined by the activity of *EXTRASPOROGENOUS CELLS/EXCESS MICROSPOROCYTES1* (*EXS/EMS1*) encoding a putative Leu-rich receptor (LRR) kinase; in *exs/ems1* plants, multiple archesporial cells per microsporangium are formed. A similar phenotype was found in mutants in *TAPETAL DETERMINANT1* (*TPD1*), encoding a putative secreted protein. Whether TPD1 is involved in the same signaling pathway, perhaps as a ligand of EXS/EMS1, remains to be clarified. The ortholog of *EXS/EMS1 MULTIPLE SPOROCYTE1* (*MSP1*) was identified in rice and mutants in maize *MULTIPLE ARCHESPORIAL CELLS1* (*MAC1*) also resemble *exs/ems1* plants. The archesporial cell divides to form a *primary parietal cell* and a *primary sporogenous cell*. The primary parietal cell divides to give rise to the *tapetum, endothecium*, and the *middle layer* of the anther. The primary sporogenous cell divides and the progeny differentiate into *microsporocytes – pollen mother cells* (PMCs) that undergo meiosis, leading to the formation of tetrads of haploid *microspores*.

Meiosis The basic processes during meiotic division I and II in plants do not seem to differ from other eukaryotes. However, in contrast to animals, there are differences in some of the cellular processes accompanying meiosis. In plant microsporocytes, the reduction of rRNA and mRNA together with plastid and mitochondria dedifferentiation and division were observed. The reason for that ''purging of sporophytic information'' is unclear. It might facilitate later gametophytic development or free the developing microspores of detrimental RNA-like viruses and silencing elements.

There are many genes found to affect plant meiosis, but only a few of them have been cloned and characterized in detail. Mutants in *SWITCH* (*SWI1*)/*DYAD* are defective in both male and female meiosis. Interestingly, male meiosis is unaffected in *swi1-1* and *dyad* mutant alleles, which might suggest distinct processes involved in the male and female germlines during meiosis in *Arabidopsis*. *SWI1* was cloned, but the putative amino acid sequence of SWI1 does not reveal similarity to any known protein. On the basis of the phenotype of *swi1* male meiocytes (absence of bivalents during meiosis), the protein is suggested to be involved in establishment of chromatid cohesion and chromosome structure during meiosis. *AtDMC1*, the *Arabidopsis* homolog of the yeast *DMC1* gene was identified and its expression was found to be specifically associated with meiosis in both PMCs in anthers and megaspore mother cells (MMC) in ovules. DMC1 in yeast, the homolog of *E. coli* recA, plays a role in homology-dependent pairing of chromosomes and chiasmata formation during meiosis. The *Arabidopsis Atdmc1* mutant shows defects in meiosis; however, in contrast to mouse and yeast, meiosis is not completely arrested; ten univalents instead of five bivalents were observed in *Atdmc1* mutant meiocytes. The absence of bivalents results in a formation of nonviable gametes with an aberrant number of chromosomes. The occurrence of double-strand breaks (DSB) is a consequence of

the *dmc1* mutation in yeast. However, the presence of DSB was not observed in *Arabidopsis dmc1* mutants. This might be explained by either efficient DNA repair systems or that DSBs do not occur in *Arabidopsis* mutant meiocytes. *arabidopsis homolog pairing2* (*ahp2*) represents another recently identified *Arabidopsis* meiosis-defective mutant. The *ahp2* mutant plants are sterile, with defects in both male and female gametophyte development. AHP2 is a homolog of the fission yeast MEU 13^+. MEU 13^+ is supposed to be involved in chromosome pairing during early prophase I and monitoring of the sequence homology of the paired chromosomes to either promotes homolog pairing or destabilizes pairing between nonhomologous ones. In good concert with that, the *ahp2* male meiocytes are characterized by the absence of bivalents during prophase I and by the presence of chromosome fragments, chromatin bridges, and unbalanced segregation in anaphase I and II.

Microspore cell wall formation After each meiotic division in species with successive cytokinesis (e.g. most of monocots) or after meiosis II in species with simultaneous cytokinesis (e.g. most of eudicots including *Arabidopsis*), the cell wall is formed between individual microspores. The cell wall is composed of *callose*, a β-1,3-glucan. Control of the division plane in plant male meiosis is achieved by an array of radial microtubules surrounding newly formed nuclei. At the interface of those microtubule arrays, the callose wall is formed either centrifugally (in case of successive cytokinesis) or centripetally (in simultaneous cytokinenesis). In *Arabidopsis*, *TETRASPORE/STUD* (*TES/STD*) gene was identified, encoding a putative kinesin. In *tes/std* mutants, formation of radial microtubule arrays at the end of meiosis is hampered and all the microspores develop in a common cytoplasm. In *tes/std* plants, few functional pollen grains are produced revealing different aberrations, for example, polyploid sperm cells. Interestingly, the recessive nature of *tes/std* mutation, together with the expression of *TES/STD* throughout the premeiotic anther, suggests sporophytic control of meiotic cytokinesis in *Arabidopsis*. Recently, the *Arabidopsis* gene *GLUCANSYNTHASE-LIKE5* (*AtGSL5*) with similarity to yeast β-1,3-glucan synthase was identified that is supposed to be involved in callose wall formation.

Individual microspores are released by the action of the enzyme *callase*, comprising endo- and exoglucanase activities, which is produced by the tapetum. This step was shown to be essential for male fertility in some species (e.g. *Petunia*). *Arabidopsis* gene *A6* is expressed in tapetum and encodes a protein similar to yeast β-1,3-glucanase and represents a candidate that may function in microspore release. Nevertheless, callose degradation was shown to be necessary but not sufficient to release the microspores in *Arabidopsis*. During microsporogenesis in *quartet* mutants, in spite of normal callose wall formation and dissolution, permanent tetrads are formed, probably as a result of persistent pectic components in the parent cell wall of the tetrad. However, in contrast to *Arabidopsis*, other species (e.g. members of *Juncaceae* and *Oenotheraceae*) produce permanent tetrads that are fully functional.

2.3.1.2 **Microgametogenesis.** Formation of haploid microspores completes *microsporogenesis,* which is followed by

microgametogenesis. The individual microspores enlarge and a single large vacuole is formed, which is associated with polarization of the microspore that subsequently undergoes two rounds of mitosis (see Fig. 5). During the first, asymmetric cell division also called *pollen mitosis I*, the nucleus is attached to the cell wall and the spindle orientation leads to the formation of a large vegetative and a small generative cell. The nucleus of the vegetative cell generally maintains irregular shape with dispersed chromatin, while the nucleus of the generative cell is highly condensed, often spindle shaped. The generative cell detaches from the cell wall (leading to the formation of the ''cell in cell'' structure) and undergoes a further round of mitosis, *pollen mitosis II*, which gives rise to the mature, three-celled male gametophyte consisting of the large *vegetative cell* and two small *sperm cells*. In species with bicellular pollen (e.g. tobacco), pollen mitosis II occurs after pollen grain germination within the pollen tube (see Sect. 2.4). In the *Arabidopsis* mutant *gemini pollen1* (*gem1*), microgametogenesis is arrested after the first mitotic division. The initial microspore polarization and phragmoplast formation seems to be affected, leading to the formation of two cells that are both able to express vegetative cell-specific markers. *GEM1* encodes a microtubule-associated protein, which was shown to bind microtubules *in vivo* and is possibly involved in the correct positioning of the phragmoplast during pollen mitosis I. The vegetative nucleus and two sperm cells after pollen mitosis II are physically connected, forming a functional assemblage, the male germ unit (MGU). The connection of vegetative nucleus is disrupted in male gametophytic mutants of two classes, *germ unit malformed* (*gum*) and *germ unit displaced* (*gud*). The penetrance of both of these male-specific gametophytic mutations is complete, suggesting functional importance of the MGU.

Pollen grain wall formation The wall of pollen grains is a complex, multilayered structure consisting of the innermost pectocellulosic *intine* and outer *exine*. The outer exine is further divided into the two-layered *nexine* (nexine I and II) with nexine I adjacent to the intine, and outer *sexine* that consists of *columella* and the outermost *tectum*. The exine is composed of sporopollenin comprising long-chain fatty acids and a minor component of phenolic compounds. Sporopollenin is polymerized from precursors secreted by the microspore and (after microspore is released from tetrad) by the tapetum. The exine forms a rigid, 3D-coat structure, providing protection against physical, chemical, and biological attacks and allowing attachment to animal pollinators and stigma surface. The exine does not develop over the entire surface of the pollen grain, creating precisely positioned germination apertures or lacunae. The number and positions of apertures could be used as taxonomic characters, for example, in fossil records. During pollen wall development, the individual layers of the pollen wall are added from the outermost layer inwards, so that the ephemeral callose wall is first deposited on the surface of the developing pollen, followed by the primexine (a precursor of the sexine), the nexine, and finally the intine. There is some evidence that genes involved in pollen wall patterning are transcribed premeiotically. However, there are very few mutations identified up to now that affect the patterning of pollen wall formation. In *Arabidopsis*, the *DEFECTIVE IN EXINE FORMATION1* (*DEX1*) gene was identified, encoding a putative membrane-associated calcium-binding protein, which

is proposed to act as a nucleation site for sporopollenin polymerization.

2.3.1.3 **Interactions of mitochondrial and nuclear genes during male gametophyte development.** The mitochondria seem to play a key role in male gametophyte development. There are many loci identified in the mitochondrial genome that are associated with so-called *cytoplasmic male sterility* (CMS). The defects cosegregating with CMS loci occur in different stages of the male gametophyte development and range from anther degeneration and a lack of fertile pollen (e.g. *Petunia*) to absence of exerted anthers (e.g. maize) and homeotic transformation of anthers into petal- or bract-like structures (e.g. carrot). Interesting feature of the CMS phenomenon in plants is the existence of nuclear located genes, so-called *fertility restorers* (referred to as Rf of Fr). Specific alleles of these genes are able to restore male fertility in CMS lines, suggesting importance of nuclear to mitochondrial genome communication during male gametophyte development. Molecular nature of this communication remains to be elucidated. However, in the last few years, substantial progress has been achieved in understanding the CMS phenomenon in plants.

Mitochondrial loci associated with CMS and mechanism of their action Most of the loci identified in CMS are the result of (often multiple) recombination events in the mitochondrial genome, leading to the formation of new open reading frames (ORFs) that could lose regulatory association with their original regulatory sequences. In CMS loci identified up to now, genes for ATP synthase subunits were often found to be involved in such recombination events. As an example, one of the best-understood CMS systems in maize could be mentioned in detail. In mitochondrial genome of maize CMS-T (Texas) male sterile line, the existence of *urf13* gene was identified, encoding a 13-kD protein. The locus is a result of multiple recombination events, leading to the fusion of primarily noncoding sequences normally found in 3′ to 23S rRNA gene that now comes under the control of a regulatory sequence of the gene encoding the 6th subunit of ATP synthase (*atp6*). At the 3′ proximity to *urf13*, cotranscribed *orf221* gene was identified, encoding a protein similar to *Arabidopsis* F_0 subunit of ATP synthase. In addition to ATP synthase subunits 4, 6, 8, and 9 coding sequences, other known sequences (e.g. cytochrome oxidase subunit coding regions) and sequences with unknown function were identified in various CMS-associated loci. The molecular nature of the defects caused by CMS-associated loci is mostly unknown. It has been found that many of the CMS-associated loci encode putative transmembrane domains. A recent hypothesis suggests that mitochondrial membrane could be a potential target for those proteins, as it has been shown in case of URF13, which forms a pore in the mitochondrial inner membrane in the presence of T-toxin produced by fungus *Cochliobolus heterostrophus*. Whether there is a naturally occurring biosynthetic product analogous to fungal T-toxin in young anthers of maize is not known.

Fertility restorers, nature, and mechanisms of action The nuclear genes found to act as fertility restorers are mostly loci found to be involved in regulation of mitochondrial gene expression; however, there are also genes that seem to work through metabolic effects. The regulation of mtDNA expression could be achieved

at both transcriptional and posttranscriptional levels, either by regulation of the mitochondrial transcription profile or protein accumulation. Good examples are *Rf1/Rf2* genes found in the restoration of the above-mentioned CMS-T in maize. *Rf1* acts as a primary CMS-T restorer and affects processing of *urf13* transcripts. *Rf2* is unable by itself to restore fertility in CMS-T lines, but it is supposed to remove residual sterility effect of *urf13* in the presence of *Rf1*. *Rf2* encodes a protein with aldehyde dehydrogenase activity and the role of RF2 could be to reduce toxic levels of aldehyde, potentially present as a result of residual *urf13* expression. In the sequence of other cloned fertility restorer genes, a pentatricopeptide (PPR) motif was often identified (e.g. *Rf* genes from *Petunia*, *Brassica*, *Raphanus*, and *Oryza*). PPR proteins were implicated in organelle gene expression in both mitochondria and chloroplasts and they seem to have different functions, for example, in RNA processing and translation or accumulation of plastid ribosomes.

2.3.2 Female Gamete Formation

There are more than 15 different patterns in the development of female gametophyte in angiosperms based on the variations in cytokinesis during meiosis, the various number of functional megaspores and the number and pattern of subsequent mitotic divisions and cellularization patterns. In more then 70% of flowering plant species, the *monosporic, Polygonum type* of female gametophyte occurs. This type of female gametophyte development can be found in many biologically and economically important species like *Zea* (maize), *Triticum* (wheat), *Gossypium* (cotton), Brassica (e.g. cabbage, kohlrabi, cauliflower, rape, mustard), and *Arabidopsis*. The basics of the *Polygonum* type of the female gametophyte development will be summarized here with an emphasis on understanding the entire process at the molecular level.

2.3.2.1 **Ovule development.** In angiosperms, the key structure where the pre- and postzygotic development takes place is the *ovule*. The female gametophyte is represented by the so-called *embryo sac*, the multicellular, mostly haploid and highly differentiated tissue, surrounded by diploid mother (sporophytic) tissue of the ovule. In *Arabidopsis*, typically 60 ovules are placed along the *replum* in the female reproductive organ, the gynoecium (the pistil). Early in flower development, *ovule primordia* differentiate from the *placenta*. During ovule development, three anatomically distinguishable and functionally distinct parts of the ovule are formed (see Fig. 6). The *nucellus*, located at the distal pole of the ovule, contains the sporogenic tissue. The growth of *inner* and *outer integuments* is initiated in the *chalaza*, located approximately in the middle of the ovule primordium. Soon after integument differentiation, elongation growth is initiated and the integuments cover the nucellus of the mature ovule except a small part at the distal pole, forming a gate for the pollen tube entry, the *micropyle*. The extended growth of the outer integument at the outer (posterior) side of the ovule results in a characteristic bending and finally the placement of the micropyle along the base (the stalk) of the ovule (Fig. 6). The position of the integument outgrowth defines the most proximal part of the ovule, which differentiates into the tissue connecting the maternal placenta tissue, the *funiculus*.

Ovule identity It seems that there are parallels between ovule and flower patterning and that those two processes

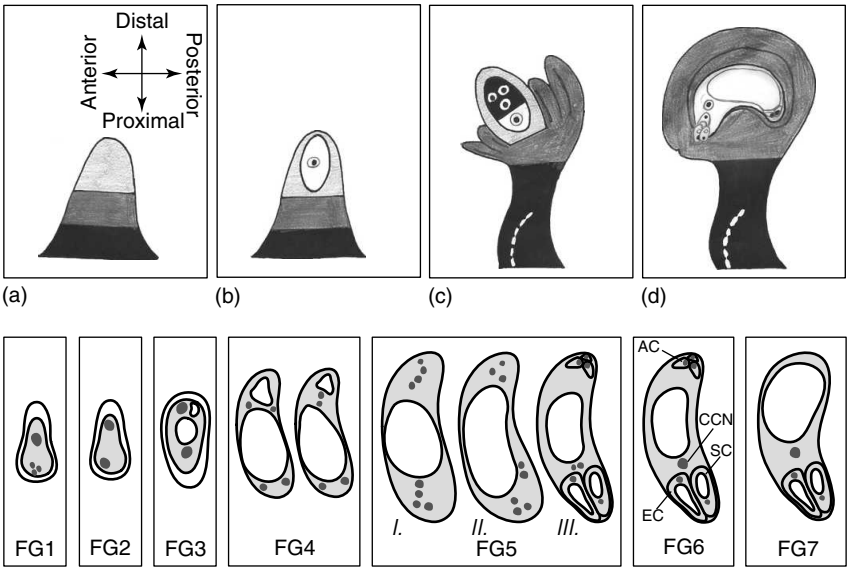

Fig. 6 Female gametophyte development. Ovule development (a–d) and individual stages of female gametogenesis (FG1–FG7) in *Arabidopsis* are schematically depicted. (a) Primary, nondifferentiated protrusion of the placenta; the proposed diversification of three future ovule regions (nucellus, chalaza, and funiculus) is depicted by different gray grades. (b) Megaspore mother cell (MMC) is differentiated. (c) Inner and outer integuments are developed; asymmetrical growth of integuments on abaxial and adaxial sides is depicted. Three of four megaspores at the distal pole will degenerate, the most proximal one will form the functional megaspore; the developing vascular tissue of funiculus is schematically shown. (d) Fully developed ovule with two synergid cells and egg cell at the micropylar (distal) pole. Drawings in a–d by Romana Dobešová (According to Grossniklaus, U., Schneitz, K. (1998) The molecular and genetic basis of ovule and megagametophyte development, *Semin. Cell Dev. Biol.* **9**, 227–238). FG1–FG7 megagametogenesis in Arabidopsis. Cytoplasm is in yellow, nuclei are in red and vacuoles are in white. EC, egg cell; SC, synergid cell; CCN, central cell nucleus; AC, antipodal cells. Only one of the two synergid cells is shown. For details of female gametophyte development see Sect. 2.3.2 (See color plate p. xxxiv).

share common factors (see also Sect. 2.2). Similar to flower organ identity acquisition, the identity of ovule primordia and ovule structures (e.g. integuments) is genetically determined and it seems to be a result of complex interactions of factors that might resemble both cadasteral and cooperative interactions found among ABCE genes during flower patterning (see Sect. 2.2.3.3). For example, the balanced activity of *AG*, the potent promoter of carpel identity in *Arabidopsis* and its homologs in *Brassica* and *Nicotiana*, was found to be necessary for proper identity acquisition of ovule primordia. AG was also shown to control *NZZ/SPL*, involved in ovule primordia patterning (see the following). In *Arabidopsis*, activity of *BELL1 (BEL1)*, encoding a homeodomain protein is crucial for the determination of ovule integument identity, possibly via negative regulation of *AG*. In this model, the AG-dependent, carpel-promoting pathway overrides effects of

integument identity genes in the absence of BEL1. BEL1, together with members of a monophyletic clade of *AG*, the MADS-box genes *SHP1, SHP2*, and *STK,* is necessary for integument identity acquisition and in the absence of these factors, integuments are transformed into carpelloid structures, possibly as a result of the above-mentioned dominance of *AG*. *SHP1, SHP2*, and *STK* have apparently redundant functions in the promotion of integument identity and *SHP1* and *SHP2* can also substitute for *AG* in carpel specification. In *Petunia*, homologs of *Arabidopsis STK FLORAL BINDING PROTEIN7* (*FBP7*) and *FBP11* share a similar expression pattern with *STK, SHP1*, and *SHP2* and in plants with lowered expression of both *FBP7* and *FBP11*, the conversion of ovules into carpel-like structures was observed. In *Arabidopsis*, the E genes *SEP1-3* collaborate with B and C genes in the acquisition of floral organ identity, probably via formation of multimeric complexes (see Sect. Multifactorial MADS-box protein complexes). Similar interactions might be involved in the ovule identity acquisition. Expression of *SEP* genes was identified in developing ovules and *SEP1/sep1, sep2, sep3* mutants show phenotype alterations similar to phenotype of *stk, shp, shp2* triple mutants (i.e. homeiotic transformation of integuments into carpelloid structures). STK, AG, SHP1, and SHP2 were shown to interact with SEP proteins in multimeric complexes, suggesting the existence of a molecular mechanism resembling those identified in acquisition of flower organ identity. In line with that, a similar situation was found in *Petunia*, where STK orthologs FBP7 and FBP11 interact with FBP2 and FBP5, putative orthologs of SEP proteins in *Arabidopsis*.

Ovule patterning The developing ovule primordium differentiates into three zones: the most distal nucellus, the central chalaza, where the integuments initiate and the most proximal funiculus. These three pattern units are distinguished very early in ovule development after the non-differentiated protrusion of the mother placental tissue appears. Recently, the first molecular evidence has become available that might explain how the supposed positional information distributed along the proximal–distal axis is interpreted into cell-fate determination. In *Arabidopsis*, the position of the inner integument outgrowth seems to be dependent on the spatial interactions of expression domains of *ANT*, encoding an AP2 domain transcription factor and *NZZ/SPL*, whose role was already mentioned in male archesporial cell differentiation (see Sect. Archesporial cell number and differentiation). The expression of *WUS*, encoding a homeodomain protein was also found to be involved in the positional specification of integument outgrowth (see also Sect. 2.2.3.2). According to a recent model, the distal expansion of proximally located expression domain of *ANT* is negatively regulated by activity of *NZZ*, and the spatial relationship between *WUS* expression in the nucellus and *ANT* in the chalaza determines the position of inner integument outgrowth. However, as *NZZ* is expressed throughout the developing ovule primordium, the spatial specificity mechanism of its negative regulation of *ANT* is so far unclear.

Integument initiation and growth Multiple factors, involved in outer integument initiation, regulation of differential integument growth, and integument extension were identified. *INNER NO OUTER* (*INO*) encoding a YABBY protein transcription

factor seems to be a specific determinant of the outer integument outgrowth. Spatial specificity of its expression depends on *ANT*, whose role was discussed in inner integument initiation (see previous section). The expression of *INO* not only seems to regulate outer integument outgrowth along the proximal–distal axis but also along the anterior–posterior (or adaxial–abaxial, recently also called *gynoapical–gynobasal*) axis (see Fig. 6). *INO* is expressed only on the posterior/abaxial/gynobasal side of the ovule, where the outer integument is initiated and exhibits extended growth, leading to the typical ovule curvature (Fig. 6). *SUPERMAN* (*SUP*) encoding a putative zinc finger transcription factor was identified to be necessary for this posterior specific location of *INO* expression domain, probably via negative regulation of *INO* positive autoregulation. However, the factors involved in the initial induction of the asymmetrical *INO* expression remain unknown. Additionally, *INO* seems to be necessary for the abaxial identity of the outer integument and its growth.

Several other factors were identified in the coordination of the inner and outer integument growth in *Arabidopsis*. For example *TSL*, encoding a Ser/Thr protein kinase (see also Sect. Development of floral organs), represents a good candidate for the molecule mediating signaling between apparently functional and evolutionarily different tissues of inner and outer integuments. Also, factors influencing growth of both inner and outer integuments were identified, for example, *DICER-LIKE1* (*DCL1*, former *SHORT INTEGUMENTS1*) encodes RNase III/RNA helicase, which might be involved in the production of small RNAs associated with the translational regulation of developmental genes during integument cell elongation.

2.3.2.2 **Megasporogenesis.** In the early phases after *Arabidopsis* ovule primordial growth initiation, an *archesporial cell* of subepidermal origin directly differentiates into the megasporocyte, the MMC. The ovule is tenuinucellate, which means that the MMC is in direct contact with the nucellar epidermis. The archesporial cell is originally established as a nonpolar, rather large cell (~17 μm in diameter), while the MMC just before meiosis is already polarized, with the majority of the organelles located at the functional pole. In a majority of species including *Arabidopsis*, the functional pole points toward the distal pole of the ovule primordium. The polarity of the megasporocyte is also reflected by the preferential accumulation of callose at the functional pole. However, the polarity is reversed in some species, for example, *Oenothera* and *Endymion*, (see also below). Activity of *NZZ/SPL* was shown to be crucial for archesporial cell differentiation in both male and female germlines (see also previous sections).

Cytokinesis in *Arabidopsis* occurs after meiosis is completed, which results in the formation of a multiplanar or linear tetrad. Molecular control of meiosis, which is mostly common for both male and female meiocytes was already discussed previously (see Sect. Meiosis). The most proximal product of the MMC meiosis survives in *Arabidopsis*, forming the *functional megaspore*. In contrast to that, in *Oenothera* and *Endymion*, the most distal megaspore survives and in some other species the surviving megaspore is not determined by position at all. The mechanisms of the functional megaspore selection are unknown, possibly both cytoplasmic determinants and

cellular interactions with neighboring cells might contribute to this.

2.3.2.3 **Megagametogenesis.** Megagametogenesis follows megasporogenesis, which ends with the formation of the functional megaspore (see previous section). Recently, megagametogenesis in Arabidopsis was described in detail. On the basis of the occurrence of anatomically distinguishable traits, the entire process was classified into seven distinct steps FG1–FG7 (see Fig. 6). During the first step, FG1 (the **F**emale **G**ametophyte 1), a functional megaspore is already differentiated; the remnants of the three degenerating meiotic products are still present. In the next development, the functional megaspore undergoes three rounds of mitosis, constituting the eight-nuclear embryo sac. In FG2, the first round of mitosis results in a two-nuclear female gametophyte, with many small vacuoles all around the cytoplasm. In FG3, the large central vacuole is formed and usually another (smaller) one at the proximal (chalazal) pole is also present. In FG4, the second round of mitosis results in the formation of a four-nuclear gametophyte, with a well-developed central vacuole. The four nuclei are organized in two pairs, located at opposite poles. The chalazal nuclei change their positions during FG4, as the line between them, originally orthogonal to the micropylar-chalazal axis, is flipped-over to become parallel with the micropylar-chalazal axis at the end of FG4. After the third (and final) round of mitosis, the eight-nuclear gametophyte is formed, defining the beginning of the most complex stage, FG5. This stage is characterized by dramatic changes in the position of nuclei; cellularization and cell differentiation takes place during FG5. FG5 was originally considered to be a rather uniform stage; however, on the basis of our results we suggested its further division into three subphases FG5 *I*–FG5 *III*. In the first subphase FG5 *I*, the embryo sac is a syncytium of eight nuclei in two groups of four, separated by the central vacuole. In FG5 *II*, the translocation of nuclei can be observed, resulting in the formation of two groups of three on both poles, and two *polar nuclei* migrating toward the position of the future central cell nucleus (CCN). The polar nucleus of chalazal origin migrates faster, which results in the asymmetric location of the polar nuclei that underlines the already preestablished polarity of the developing embryo sac. Both these stages are rather short, as the frequency of the ovules found in both FG5 *I* and FG5 *II* is very low. In FG5 *III*, cellularization and cell differentiation occurs. At the end of the phase, the two *synergid cells* (SCs) with well-developed vacuoles can be distinguished surrounding an *egg cell* on the *micropylar* (distal) *pole*. At the opposite, *chalazal* (proximal) *pole*, three *antipodal cells* (ACs) are distinguishable; the *central cell* is still not fully differentiated. The end of FG5 is defined by the fusion of polar nuclei that leads to the formation of the diploid nucleus of the central cell. In FG6, the antipodal cells undergo cell death, thus forming the four-celled mature female gametophyte (FG7), where double fertilization triggers embryo and endosperm development, giving rise to a fully functional seed (see Sects. 2.4 and 2.5). In some species (e.g. maize), the antipodal cells do not degenerate but proliferate, forming a cluster of up to 40 cells at the chalazal pole (ChP).

2.3.2.4 **Molecular nature of female gametophyte development.** In spite of the crucial importance of the female gametophyte tissue in the entire plant life

cycle, the factors necessary for proper formation and function of mature embryo sac are mostly still unclear. Just in the last decade, extensive mutation screens specifically directed to identify female gametophyte mutations were performed. On the basis of the process affected, female gametophytic mutations could be classified into six phenotypic categories and very recently, the molecular nature of the involved factors is being discovered. Interestingly, the largest group of mutants that has been defective in female gametophyte development or function seems to affect postfertilization processes. This fact suggests importance of maternal control of postfertilization processes in *Arabidopsis* and possibly also in other plant species (see also Sect. 2.5).

First gametophytic mutation with impact on female gametophyte development, which was characterized at the molecular level, is *gametophytic factor2* (*gfa2*). The *GFA2* gene encodes a J-domain containing protein targeted to mitochondria. *GFA2* was shown to partially complement the yeast mutation *mitochondrial DNAJ homolog1 (mdj1)*, a gene for a chaperone in the mitochondrial matrix and *GFA2* is supposed to be an *Arabidopsis* ortholog of the yeast *Mdj1p*. The *GFA2* gene was found to affect both female and male gametophyte. The penetrance of *gfa2* in the female gametophyte is almost complete and a substantial part of the male gametes is affected (99 and 86%, respectively). Female gametophyte development in *gfa2* embryo sacs is terminated at FG5. Synergids of the mature female gametophyte were suggested to be a source of the diffusive attractants mediating signaling that directs the pollen tube into the micropyle (see also Sect. 2.4.1). In *Arabidopsis*, cell death of one of the synergids occurs as a consequence of pollen tube entry into the micropyle or just before pollen tube arrival (for more details see Sect. 2.4.2). However, pollen tube entry did not induce synergid cell death in *gfa2* mutants. In spite of incomplete megagametogenesis that prematurely terminates at FG5, the *gfa2* mutant ovules were still able to attract pollen tubes. This might suggest functional independence of synergid cells in the final stages of megagametogenesis, at least in terms of their functionality in pollen tube attraction. The other female gametophyte mutant that is well characterized at the molecular level is *nomega*. The ovules in *nomega* mutants were found to be arrested at the FG2 phase of megagametogenesis. The *NOMEGA* gene was found to encode a homolog of the APC6/Cell Division Cycle (CDC) 16 subunit of the Anaphase Promoting Complex/Cyclosome (APC/C), which is a part of the APC/C complex, and which together with the SCF pathway represents a key regulatory component in cell cycle regulation by ubiquitin-dependent proteolysis in yeast. The APC/C complex was found to be involved in the degradation of Cyclins A and B in clam and *Xenopus*. In the *nomega* mutant embryo sacs, the absence of Cyclin B degradation was shown. The APC/C complex was also found to be involved in the earlier checkpoint of the cell cycle, the degradation of the anaphase inhibitor securin, thus facilitating the separation of chromatids. Therefore, a functional APC/C complex seems to be necessary for cell exit from mitosis. The ability of the *nomega* mutant embryo sacs to accomplish the first mitosis is explained by the residual activity of the APC/C originating from the MMC, which is sufficient for metaphase to anaphase progression. The later checkpoint allowing exit from first mitosis and leading to the formation of the two-nuclear

embryo sac might be overcome by inactivation of the CDK1 mitotic complex by phosphorylation. The absence of central vacuole formation in the *nomega* mutants remains unclear.

2.3.2.5 **Sporophyte to gametophyte communication during female gametophyte development.** In contrast to fucoid algae, where the polarity of the naked zygote is dependent on external environmental signals, embryo sac polarity in *Arabidopsis* is fully position dependent. On the basis of current genetic data, an interregional interaction between the developing female gametophyte and surrounding sporophytic tissue representing two consecutive generations seems to be crucial for proper embryo sac assembly and development. Presence of strong mutant alleles of *bel1, sin 1*, and *ant* genes, involved in the formation of the ovule sporophyte (see also Sect. Ovule patterning), results in the early arrest of embryo sac development in *Arabidopsis*. Further, despite the fact that the ovule sporophyte and female gametophyte tissue development have been genetically dissected, the presence of at least inner integument seems to be a prerequisite for successful embryo sac development. This might suggest either functional dependency and/or common check point, respectively, linking female gametophyte and ovule sporophyte development. A role for positional cues transmitted by sporophytic tissue adjacent to the developing embryo sac was suggested in the regulation of female gametophyte development.

Mutations in *CYTOKININ INDEPENDENT1* (*CKI1*) result in the abortion of megagametogenesis at transition from FG5/FG6. Degeneration of chalazal nuclei at FG4 and distortion and later degradation of the central vacuole, coupled with mispositioning of some of the nuclei at FG5 *III* represents one of the first anatomically distinguishable traits in the *cki1* mutant embryo sacs. In terminal *cki1* mutant phenotypes, pleiotropic effects were observed, including different degrees of embryo sac degradation and increased number of nuclei. Thus, the *cki1* mutant phenotypes might imply importance of the central vacuole for the timing and spatial distribution of specific cellular events, for example, mitosis during megagametogenesis. CKI1 is a putative receptor histidine kinase that belongs to the two-component signaling system and it is presumed to act in communication between ovule sporophyte and female gametophyte generations in *Arabidopsis*. However, despite various experimental efforts, the signaling molecule recognized by CKI1 remains unknown.

2.4 Angiosperm Fertilization

Double fertilization in flowering plants involves a complex series of interactions between gametophytes and sporophyte, which results in the fusion of sexual cells and nuclei.

2.4.1 Progamic Phase

2.4.1.1 **Sporophyte–gametophyte interactions.** In angiosperms, the *pistil* (gynoecium) in the central part of the flower represents the pollen-accepting organ, which has multiple functions in plant reproduction: it decides whether to accept or reject the pollen, sustains pollen tube growth, and forms and protects the female gametophyte inside the ovule. The pistil is composed of one or more fused *carpels* that bear the *ovules*. Carpel fusion occurs very early in pistil development. Inner tissues of the developing upper pistil part differentiate to form the specialized secretory zone

of the stigma at the top of the style and the transmitting tissue within the central cylinder of the style. In some species, the style remains hollow, with only one layer of secretory tissue lining the inner surface of the cylinder. At flower maturity, when pollination takes place, the pistil is fully developed and composed of the *stigma*, the *style*, and the *ovary*. The morphology of anthers and pistils coevolved with the mode of pollen dispersal. Different mechanisms of pollen release, pollen transfer, and its deposition to the female sexual organs have developed in plants during evolution.

Numerous *interactions* between the sporophyte and gametophyte include signaling and nutrition. The first interactions take place on the stigma surface after pollen grain landing, where the pollen grain hydrates and germinates forming a *pollen tube*, followed by the penetration of the pollen tube through the specialized tissues of the pistil, – the stigma, and the style. Finally, the pollen tube bearing the two sperm cells reaches the female gametophyte, the *embryo sac*, located inside the *ovule* in the *ovary*. Pollen tube guidance at this stage is influenced by interactions between pollen tube and *micropyle exudates* and the *filiform structures* of the *synergids*.

2.4.1.2 **Stigma types and their role in pollen attachment and hydration.** Appropriate temporal coordination of stigma development is crucial for receptivity, which is defined as the ability to attach pollen by adhesion, to facilitate pollen hydration and subsequent germination, leading to the formation of a pollen tube. Two basic types of the stigma influence the mode and place of the first sporophytic cell–gametophytic cell interaction. *Dry stigmas* are characteristic with surface cells protruding as papillae, which are covered by a primary cell wall, a waxy cuticle and proteinaceous pellicle. During the receptive stage, the cuticle is broken either by visiting insects, due to the activity of some enzymes such as esterases or cutinases or by increasing stigma cell turgidity. The surface of *wet stigmas* is covered by a viscous layer of exudates containing lipids, proteins, polysaccharides, and pigments produced by the surface cells or by cells of the secretory zone of the stigma. A thin layer of water is found beneath this viscous layer.

Pollen grains are shed either in a bicellular or in a tricellular condition and are transferred to stigmas by pollinators either biotic (such as insects, birds, or animals) or abiotic (mainly wind, and less frequently, water). The first interactions of the proteins and lipids of the pollen coat and proteins of the stigma surface follow pollen capture mediated by the structure of exine. A cysteine-rich protein with similarity to lipid transfer proteins called STIGMA/STYLAR *Cys*-RICH ADHESIN (SCA) and pectic polysaccharide are required for pollen tube adhesion in lily. In Brassica with a dry stigma, *S-LOCUS-RELATED PROTEIN* (*SLR1*) is a stigma-expressed gene related to the *S*-glycoprotein, which is involved in self-incompatibility (SI) (see Sect. 2.4.3).

Recently, general similarities were found in the pollination of dry and wet stigmas; the presence of lipids modulates water transfer to the desiccated pollen and tube penetration, while highly diverse proteins and peptides mediate self and foreign pollen recognition as well as pollen tube growth. Hydration of pollen grains, which are dehydrated and metabolically quiescent when they are released from anthers, seems to be actively regulated on stigmas. Hydration induces pollen grain activation, subsequent germination, and pollen tube formation. Ultrastructural

rearrangements during pollen activation are mainly connected with the endomembrane systems, such as expansion of ER, appearance of dictyosomes and secretory vesicles. Polarized migration of organelles to the domain of pollen aperture is observed just before pollen tube emergence. The cytoplasm of the vegetative cell exhibits a rotational or streaming movement and passes into the tip of pollen tube followed by the movement of the MGU (see Sect. 2.3.1.1). Pollen tube penetration of the stigma surface is controlled by means of various enzymes. Activities of numerous hydrolases, such as acid phosphatase, esterases (e.g. cutinase), pectate lyase, ribonuclease, and protease, were localized to the walls of pollen grains and tubes; while cutinase inhibitors that can significantly reduce the ability of the pollen tube to penetrate the stigma were detected in stigma cells. Enzymatic penetration of the stigma is strictly controlled, which demands communication between pollen tube and the stigma. Receptor kinases are supposed to be mediators of such communication (e.g. *Lycopersicum esculentum* PROTEIN RECEPTOR KINASE1 (LePRK1) and (LePRK2)). The pollen specific cysteine-rich protein LATE ANTHER TOMATO52 (LAT52), which is essential for pollen hydration and germination *in vitro* and for normal tube growth, interacts *in vivo* with LePRK2. Other proteins like PISTIL POLLEN ALLERGEN-LIKE (PPAL) protein with similarity to β-expansin, LIPID TRANSFER PROTEIN (LTP) or SCA were detected in stigma exudates. These proteins are members of a signaling system that regulates pollen adhesion, germination, and pollen tube growth.

2.4.1.3 **Pollen tube growth.** Pollen tubes are among the most rapidly extending cells. These growth rates are possible due to a highly polarized apical fusion of vesicles, which transports cell wall components to the growing tip. A tip-focused cytoplasmic Ca^{2+} gradient is known to play a central role in the regulation of pollen tube growth. Modulation of the cytoplasmic Ca^{2+} concentration results in changes in the rate and direction of pollen tube growth. It was found that increases in GTP levels could promote pollen tube growth. Rop GTPases have been implicated in the regulation of pollen tube growth probably by interaction with the tip-focused Ca^{2+} gradient.

The growth of pollen tubes through the style is promoted by products of the secretory cells in the transmitting tissue of the central core of solid (closed) styles or those of the canal lining in hollow (open) styles. The cells of the transmitting tissue form a continuous connection with the cells of the stigma secretory zone. Longitudinal walls of the transmitting tissue cells are separated by extracellular matrix that contains a mixture of sugars, proteins, and phenolic compounds. Hyp-rich glycoproteins (HRGPs) like arabinogalactan proteins, PISTIL-SPECIFIC EXTENSION-LIKE PROTEIN (PELP), TRANSMITTING TISSUE-SPECIFIC (TTS) and GALACTOSE-RICH STYLE GLYCOPROTEIN (GaRSGP) form an intercellular matrix that serve as a source of nutritive and regulative compounds for tobacco pollen tube growth. A gradient of TTS protein glycosylation in the styles of tobacco or a gradient of γ-aminobutyric acid (GABA) in *Arabidopsis* pistil could function as possible mechanisms for the control of pollen tube growth. Pollination of the stigma also triggers a cascade of responses in distal flower organs. It was found that ethylene and its biosynthetic precursor 1-aminocyclopropane-1-carboxylate (ACC)

play an important role in the regulation of these responses. Analysis of ACC metabolism showed that pollination induces high ACC–oxidase transcript levels in all cells of the transmitting tissue, while the ACC-synthase transcripts accumulate in a wavelike pattern in which the peak coincides with the front of the ingrowing pollen tube tips. This wave of ACC-synthase expression can also be induced by incongruous pollination and partially by wounding indicating that pollen tube invasion displays similar features to wounding and such effects might be recruited for evoking the postpollination response. Barriers preventing incorrect pollination negatively affect pollen tube growth in the pistil (see Sect. 2.4.3.).

Within the ovary, the pollen tube is guided on the surface of the placenta and the funiculus toward the micropyle of the *receptive ovule*. The most common way of pollen tube entry to the embryo sac located inside the ovule is through the opening in the ovule integuments, the micropyle. Attraction signals for pollen tube growth could include calcium accumulation in the synergid during embryo sac maturation, as well as other chemotropic signals created near micropylar region by various ovule structures (e.g. micropylar cells of the nucellus, the inner integument or the filiform apparatus of synergids). Presence of proteins, RNA, and carbohydrates has been demonstrated in the micropylar region. Thus, it can be concluded that numerous checkpoints exist along the whole pollen tube pathway, which provide active signaling that guides the pollen tube to its destination, the embryo sac.

2.4.2 Syngamic Phase: Karyogamy and Plasmagamy, Double Fertilization

The pollen tube enters the embryo sac through the *receptive synergid*. The signs of the synergid receptivity are: (1) cytoskeleton reorganization, (2) Ca^{2+} accumulation, and (3) degeneration of organelles and plasma membrane. The pollen tube develops an aperture on the tip and discharges its contents into the receptive synergid or in the space previously occupied by this synergid (depending on the time of the synergid degeneration). Pollination initiates disintegration of one of two synergids, which were identical before pollination. The mechanism of this process initiation at the molecular level is still unclear. In some species, synergid cell death occurs even in the absence of the pollination, suggesting that the process might be an intrinsic feature of megagametogenesis.

DNase degrades both the vegetative cell nucleus and the nucleus of the synergid and the sperm cells are transferred to the egg and central cells. Bundles of actin filaments form two corona-shaped structures; one is located near the egg nucleus and the other near the central cell. Coordinated actions of actin and myosin on the sperm cell surface mediate sperm cell transport to the position near the egg cell and the central cell nuclei. Regulation of the actin-corona formation is not yet fully known. The cell walls of the egg cell and the central cell are modified and surrounded only by the cell membrane that facilitate delivery of the sperm nuclei with the male cytoplasm. This delivery is initiated by the apposition of plasma membranes of the sperm and the egg and those of the second sperm cell and the central cell. *Double fertilization* includes both: two nuclear fusions (*karyogamy*) and the coalescence of male and female cytoplasm (*plasmagamy*). The first karyogamy (syngamy) is the fusion of the egg and sperm cell nuclei,

which produces the diploid nucleus of the *zygote*. Measurements of calcium concentration during *in vitro* fertilization of maize egg demonstrated that fusion of gametes triggers a calcium influx, which is then followed by an increase of cytoplasmic calcium (similarly as in animal systems). The second karyogamy, occurring only in angiosperms, is the fusion of the (usually) diploid nucleus of the central cell with the second sperm cell nucleus forming the triploid *primary endosperm nucleus*. Plasmagamy can be conditioned by the female gametophyte as, in some cases, male cytoplasm is excluded from the egg cell. It seems that despite morphologic uniformity of the two sperm cells, some differences on their surface may allow specific trafficking either to the egg or to the central cell. Formation of MGU could significantly influence sperm cell traffic.

2.4.3 Prezygotic and Postzygotic Barriers to Fertilization

Various physiological or genetic barriers can preclude successful fertilization. Male or female sterility, which arrest normal development of gametes, is one example of such a genetic barrier. Furthermore, other mechanisms called *incompatibility* exist, which are defined as the inability of functional gamete fusion. Many types of intraspecific and interspecific incompatibility have developed in plants to prevent inbreeding on the one hand (self-incompatibility) and on the other to maintain stability of species preventing gene flow between unrelated species (cross-incompatibility, incongruity). These reproductive strategies can function either as prezygotic barriers that inhibit pollen tube growth or as postzygotic barriers causing embryo abortion.

2.4.3.1 **Self-incompatibility.** The widely distributed mechanism of the prezygotic barrier named *self-incompatibility* (SI) is an inherited phenomenon, by which plants can recognize and reject their own pollen by inhibiting pollen hydration, germination, and/or tube invasion and thus block the delivery of sperm cells to the ovary and prevent inbreeding. Variants of self-incompatible systems were classified according to different aspects. On the basis of flower morphological differences, heteromorphic, and homomorphic types of SI, are distinguished. *Heteromorphic SI* is characterized by floral polymorphism. Flowers of species with heteromorphic SI vary in position, size, or shape of the reproductive floral organs. Nevertheless, most of the self-incompatible plants are of a *homomorphic type*. Plants with this type of SI produce morphologically identical flowers. Homomorphic SI is further divided into sporophytic and gametophytic types according to determination of successful pollen phenotype. In *sporophytic SI*, the pollen phenotype is determined by the genotype of parent; while in *gametophytic SI*, the pollen phenotype is determined by its own genotype. A single locus with multiple alleles named the *S-gene* (*STERILITY*) represents the genetic basis of self-incompatibility. Later, two separate genes at the S-locus were distinguished that control male and female specificities. In sporophytic SI, pollen rejection occurs on the stigma surface when the pollen parent has one or both S-haplotypes in common with the pistil, independently of the S-haplotype of the pollen grain. Inhibition of pollen tube growth in case of more frequent gametophytic self-incompatibility occurs mainly in the upper part of the style in the case in which S-haplotype of the pollen matches either one of the two S-haplotypes in the

pistil. Gametophytic SI in the *Poaceae* family is genetically controlled by two unlinked multiallelic loci S and Z. Alleles of both S and Z need to match in the pollen and pistil to reject pollen.

2.4.3.2 **Mechanisms of self-incompatibility.** It is now known that the common phenomenon of self-incompatibility is not realized uniformly by all flowering plants, since several biochemically distinct mechanisms of S-locus expression were revealed among different families. (1) Gametophytic SI mechanism in Solanaceae, *Rosaceae*, and *Scrophulariaceae* involves *S-RNase*-mediated degradation of RNA in own pollen tubes. Several variants of a receptor or inhibitor models explaining this mechanism were proposed. (2) The *Papaveraceae* gametophytic SI mechanism represents *S-protein*-mediated signal transduction cascade via Ca^{2+}, phosphoinositides, protein kinase, and phosphatases in pollen tubes. Actin cytoskeleton was found to be a target for signaling pathways involved in this SI response. (3) Mechanism of the sporophytic SI in *Brassicaceae* is based on the different genes of S-locus that control male and female specificity. Stigma specific proteins S-LOCUS-SPECIFIC GLYCOPROTEIN (SLG) and S-LOCUS RECEPTOR KINASE (SRK) are associated with self-incompatibility in the pistil, while S-LOCUS CYSTEIN-RICH/S-LOCUS PROTEIN-11 (SCR/SP11) represents the pollen specific S protein.

2.4.3.3 **Incongruity.** Interspecific incompatibility caused by evolutionary divergence is based on the absence of information that leads to an incomplete spatial and temporal coordination in the plant reproduction process.

2.4.4 *In Vitro* Fertilization

Experimental approaches for the study of fertilization or overcoming incompatibility involve methods of *in vitro* pollination/fertilization such as intraovarian pollination, test tube pollination of segments of the placenta with ovules, and *in vitro* fusion of isolated, single gametes.

2.5 Embryo and Endosperm Development

Fertilization of the female gametophyte in angiosperm plants initiates a process of coordinated development of embryo, endosperm, and seed coat, which ensures the production of a viable seed. It is more than a century since *double fertilization* was discovered. After pollination, two sperm cells, delivered by a pollen tube, fuse with the *egg* and *central cell*, which results in the formation of the *embryo* and endosperm, respectively. The embryo and endosperm both develop within the confines of the maternal tissue (seed coat), but each follows a different developmental program. Within the embryo, the basic body plan of the mature plant is laid down, whereas the ''life-history'' of the endosperm is far shorter and limited to the seed development stage. Nevertheless, the endosperm fulfills essential functions in nourishing the developing embryo and controlling the whole seed development process. It is also important to note that the endosperms of plants, including cereal species such as rice, maize, wheat, and barley represent one of the most important renewable sources of food and raw materials.

2.5.1 Endosperm Development

Endosperm development is initiated by the union of the haploid sperm cell and the diploid central cell. Three main types of

triploid endosperm can be distinguished depending on coupling between nuclear and cell divisions. The most common form of endosperm is the so-called *nuclear type*, which involves a phase of free-nuclear (syncytial) division that is not accompanied by cytokinesis. On the other hand, the *cellular type* of endosperm develops via a series of mitotic divisions always coupled with cytokinesis. A third possibility is provided by *helobial type*, in which the proendosperm divides to give rise to two daughter cells, one of which undergoes cellular type of development, whereas the other undergoes nuclear type of development.

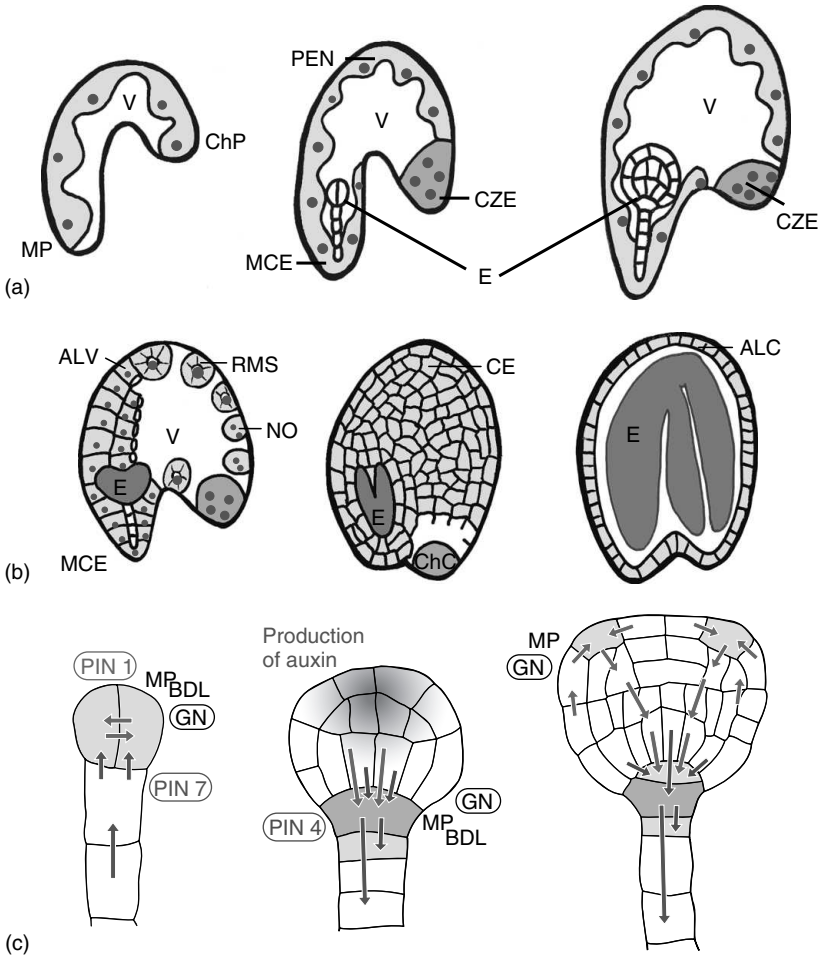
2.5.1.1 **Evolutionary aspects of endosperm development.** Interestingly, gymnosperms instead of developing true endosperms possess characteristically enlarged female gametophytes that accumulate nutrients before fertilization. Thus, from an evolutionary point of view, the endosperm can be viewed as a functional homolog of the gymnosperm female gametophyte. Many aspects of nuclear-type endosperm development appear to have been repeatedly sequestered from preexisting mechanisms found in female gametophytes of land plants. Both female gametophytes and nuclear endosperms undergo multiple rounds of free-nuclear divisions forming a multinucleate *syncytium* and later arrangement of nuclei into nucleoplasmic domains via the establishment of radial microtubule arrays. Finally, *cellularization* (formation of cell walls around the nuclei and surrounding regions) is achieved through the formation of tubelike structures termed *alveolus* (ALV). Genetic evidence also supports a common mechanism in the regulation of endosperm and female gametophyte since a number of mutants have been isolated, which are affected in both these processes.

2.5.1.2 **Development of nuclear endosperm.** The nuclear-type endosperm is the most common type in angiosperms including dicot *Arabidopsis* and monocot cereals. Owing to availability of molecular markers for different endosperm compartments and developmental stages, most of the information on nuclear endosperm development has been obtained from studies in *Arabidopsis*. The young *Arabidopsis* endosperm can be divided into three *domains*: the *micropylar endosperm* (MCE), which surrounds the embryo, the *peripheral endosperm* (PEN), which fills most of the seed volume, and the *chalazal endosperm* (CZE) in the nucellar region.

Nuclear endosperm development is characterized by stages of *syncytial nuclear divisions* (Fig. 7a) followed by *cellularization* (Fig. 7b). The whole syncytial endosperm stage can be divided into nine substages, each representing one of eight rounds of mitotic divisions. After the initial three synchronous division cycles, the mitotic activity of MCE, PEN, and CZE occurs independently, with nuclei dividing synchronously within domains. Nuclear divisions have never been observed directly in the CZE after the three synchronous rounds of division. Increased signal intensity of the labeled histone in the CZE nuclei together with the absence of nuclear divisions in CZE suggests that these nuclei undergo endoreduplication. At the final stage, the syncytial endosperm contains 200 nuclei.

The cellularization process starts as a wave in MCE, progressing through PEN and CZE at different rates and with significant variations between the different parts. When the cellularization around the embryo in MCE is completed, the PEN is

still syncytial, whereas CZE remains syncytial until late stages of seed maturation. Cellularization in *Arabidopsis* as well as cereals involves repeated rounds of formation of a *radial microtubule system* (RMS) emanating from nuclei and enclosure of nuclei with RMS in a tubular cell wall structure (*alveolus*) (Fig. 7b). In PEN, the process of cellularization starts with the occurrence of RMS at the nuclear surface and subsequent formation of cytoplasmic *phragmoplasts* in interzones between RMS. The phragmoplasts mediate formation of tubular alveolus, which encloses the nucleus with its RMS. Nuclei within the alveoli undergo synchronous periclinal division leading to formation of peripheral cells and internal alveoli. The cellularization process in MCE also occurs via RMS and cytoplasmic phragmoplasts, but because of spatial constraints, alveoli typically do not form. The cellularization process for *Arabidopsis* results in a completely cellular endosperm except for a small area in the CZE adjacent to the chalazal cyst (ChC).



As the *Arabidopsis* embryo grows, the cellular endosperm is gradually depleted, which contrasts with the persistent endosperm of the cereals. In the mature *Arabidopsis* seed, a massive embryo fills the ovule and only a single peripheral layer (the *aleurone layer*) with unknown function persists. It is assumed that the nonpersistent endosperm supports the developing embryo and this support function is later taken over by the cotyledons during germination.

Despite obvious differences in some aspects of endosperm development between *Arabidopsis* and many monocots including cereals, the cellularization processes reveal striking similarities. Importantly, the process of cellularization by RMS formation also occurs during the cellularization process in a number of other systems, including sporogenesis in lower plants, male and female gametophyte development in gymnosperms and angiosperms, and embryogenesis in gymnosperms. Thus, the findings obtained from studies on *Arabidopsis* and the endosperm of cereals have more general validity in our understanding of plant development.

2.5.2 **Embryo Development**

Embryogenesis is a process that transforms a single-celled zygote into the embryo containing all the basic pattern elements of the future plant. Unlike in higher animals, where the embryo is a miniature variant of the adult, the juvenile form of the

Fig. 7 Development of the endosperm coenocyte in the *Arabidopsis* embryo sac. (a) Endosperm nuclei migrate from the micropylar pole (MP) toward the chalazal pole (ChP) of the embryo sac. A large central vacuole (V) fills up most of the volume and is surrounded by cytoplasm. Cytoplasm is in yellow, nuclei are in red and vacuole is in white. As development progresses, the coenocyte forms three distinct domains: (1) the region surrounding the embryo (MCE); (2) the peripheral endosperm (PEN); and (3) the region of the chalazal endosperm (CZE), which contains the chalazal cyst (ChC). At the end of the globular embryo stage, the embryo (E) becomes completely surrounded by cytoplasm (Modified according to Olsen, O.A. (2004) Nuclear endosperm development in cereals and *Arabidopsis thaliana, Plant Cell* **16**(Suppl. 1), S214–S227). (b) Endosperm cellularization in Arabidopsis: the endosperm at the late globular embryo stage shows a cellular endosperm in MP, a gradient of stages in the alveolation process in PEN, and endosperm nodules (NO) as well as chalazal cyst (ChC) formation in ChP. During alveolation, radial microtubule system (RMS) emanates from the nuclear membranes, cell walls form tubes or alveoli (ALV) around each nucleus with open ends toward the central vacuole (V). Later, endosperm becomes completely cellular (CE). The endosperm is consumed during seed maturation, leaving only the peripheral aleurone-like cell (ALC) layer in a mature seed (Modified according to Olsen, O.A. (2004) Nuclear endosperm development in cereals and *Arabidopsis thaliana, Plant Cell* **16**(Suppl. 1), S214–S227). (c) Model for a role of auxin distribution in embryo patterning: two-cell stage embryo – specification of the apical cell. Auxin accumulates (depicted in green) in the proembryo by PIN7-dependent transport (red arrows) through the suspensor. Auxin response (*mp, bdl*) and transport (*gn*) mutants show defects in the establishment of the apical cell. Young globular embryo – specification of the root pole. Auxin production is established in the apical part (purple) and auxin transport routes reverse. Auxin accumulates, in a PIN1- and PIN4-dependent manner (blue and purple arrows) in the hypophysis and is further transported through the suspensor. *mp*, *bdl*, and *gn* show defects in root pole establishment. Early heart (triangular) stage – establishment of cotyledons. Most auxin is still transported to the basal part of the embryo and then further through the suspensor. New sites of auxin accumulation emerge at the tips of forming cotyledons. MP and GN are also involved in cotyledon establishment. (See color plate p. xxx).

plant (*seedling*) shows only basic pattern elements, which can be strongly modified by elaborated postembryonic development. The seedlings of different higher plant species are remarkably uniform. They display a main *apical–basal axis* of polarity, with the shoot meristem at the apical end and root meristem at the basal end and the *radial pattern* of tissue layers, which are arranged concentrically. This basic embryonic pattern is then postembryonically elaborated mainly by the activity of the *meristems* (permanent stem cell populations) and *de novo* organogenesis, which can lead to a great increase in architectural complexity and which generates most species-specific features of the adult plant.

2.5.2.1 **Pattern formation in *Arabidopsis* embryogenesis.** In the progression of plant embryogenesis, three main patterning events can be distinguished: the generation of the apical–basal axis, formation of radial pattern and establishment of bilateral symmetry. In different higher plant species, the mature embryos show the same basic patterning elements; however, the early pattern of cell division during embryogenesis is not uniform between species. Therefore, it is unclear how important the early patterning events are. By far, most of the information on mechanisms of embryonic patterning comes from the studies in *Arabidopsis* and other *Brassicaceae*. These species display an exceptionally regular and reproducible pattern of cell divisions during embryo development.

The apical–basal pattern in *Arabidopsis* has been traced back to the earliest stages of embryogenesis. The zygote has an asymmetrically positioned nucleus with a vacuole, which elongates in a polar manner at the apical end. The zygote divides asymmetrically and produces a small *apical cell* and a larger *basal cell*. The apical cell divides vertically and generates the "*proembryo*," which later gives rise to most regions of the seedling including the shoot meristem. The basal cell continues to divide horizontally and produces the *suspensor* – a single file of cells that attaches the proembryo to maternal tissue. At the early globular stage, the uppermost cell is specified to become the *hypophysis* – the founder of the root meristem. Thus, both apical and basal ends of the future seedling are established. This initial apical–basal subdivision is also reflected molecularly: for example, genes encoding the transcription factors AtML1 or WUS are expressed exclusively in the apical cell lineage, whereas specific arabinogalactan epitopes or a regulator of auxin transport PIN-FORMED7 (PIN7) were detected in the basal cell lineage of early embryos.

The formation of the radial pattern initiates at the eight-cell stage of the proembryo. These cells divide periclinally and set apart the primordial epidermis (*protoderm*). At the next stage, the inner cells divide vertically producing outer ground tissue and inner provascular cells. Thus, the globular embryo is composed of a radial pattern consisting of three concentric cell layers that later develop into epidermis, ground tissue (endodermis and cortex), and vascular tissue of the seedling. The early marker of embryonic ground tissue is the transcription factor SCARECROW (SCR), which has been shown in roots to be required for endodermis specification. Interestingly, SCR transcription is regulated by a homologous factor SHORTROOT (SHR), which moves into the endodermis from the cells of vascular bundle, where it is expressed.

At the early heart (triangular) stage, early patterning is completed with the

establishment of bilateral symmetry, which is manifested by the initiation of two symmetrically positioned embryonic leaves – *cotyledons*. The initiation of cotyledon primordia is preceded by production of transcription factor ANT, which is required for maintaining the proliferative cell state during various organogenesis processes.

The early patterning is followed by a phase of growth and elongation of organs that merely elaborate already prelaid architecture. The next and last phase of embryo development (embryo maturation) is characterized by accumulation of storage reserves that include lipid, starch, and protein bodies within embryo cells. Hereafter, the seed dries and becomes separated from the mother plant. After seed dormancy is overcome, germination occurs and the embryo gives rise to a seedling.

2.5.2.2 **Lessons from embryo mutant screens.** The mechanisms that govern patterning processes in *Arabidopsis* embryogenesis have been addressed mainly using genetic approaches. In mutant screens for genes encoding the regulators of embryo development, mutants were categorized by seedling phenotypes and by early embryonic division patterns.

Morphogenetic embryo mutants Many of the mutants recovered from these screens were found to be involved in basic cellular processes that only subsequently affect pattern formation. Cytokinesis mutants such as those in the *KNOLLE* (*KN*) gene (encodes a cytokinesis-specific syntaxin) or its interactor *KEULE* (*KEU*) (the yeast Sect. 1 homolog) fall into this category. Both these mutants are affected in vesicle fusion in the plane of cell division, which results in incomplete cell walls and multinucleate cells.

Other mutants are defective in the proper orientation of the plane of division rather than in cell division *per se*. These are, for example, *fass* mutant embryos, which are made up of irregularly shaped and enlarged cells. *FASS/TONNEAU2* (*FASS/TON2*) encodes a type 2a protein phosphatase and seems to be required for the formation of ordered microtubular arrays that make up the plant cytoskeleton. Also members of the *pilz* and *titan* (*ttn*) groups of mutants have abnormally formed embryos as a result of cytoskeletal defects that interfere with mitosis and cytokinesis. The *pilz* mutant embryos contain actin but lack microtubules, which results in a mushroom-shaped embryo with one or a few large cells. *TTN5* encodes a small G-protein Arl2 with a possible role in regulation of vesicle trafficking, whereas other genes of the *pilz* group encode orthologs of mammalian tubulin-folding cofactors.

Another class of mutants that shows more pleiotropic defects during embryogenesis is defective in genes involved in sterol biosynthesis such as *STEROL METHYLTRANSFERASE1/CEPHALOPOD* (*SMT1/CPH*), *FACKEL/HYDRA2* (*FK/HYD2*), and *HYDRA1* (*HYD1*). Early embryo defects in cell division and expansion in these mutants result in embryos with abnormally shaped cotyledons and reduced central and basal regions; however, the exact role of sterols in embryogenesis is unclear.

In summary, molecular analysis of morphogenetic mutants did not provide much insight into plant patterning mechanisms, but provided important entry points into molecular studies of basic cellular functions such as vesicle trafficking and cytoskeleton arrangement.

Pattern formation embryo mutants Most of the mutants specifically affected in embryo patterning processes were identified by loss or alterations in apical–basal or radial pattern elements at the seedling stage. In contrast to the many transcription factors revealed by similar screens in animal systems such as *Drosophila*, only a few transcriptional regulators were found in *Arabidopsis*.

Several mutants with apical-basal patterning defects, such as *monopteros* (*mp*), *bodenlos* (*bdl*), *auxin resistant6* (*axr6*), or *gnom* (*gn*), have been isolated. All these mutants show deletion of basal structures (root and occasionally hypocotyl) and variable defects in formation of apically positioned cotyledons. *MP* encodes the transcriptional activator AUXIN RESPONSE FACTOR 5 (ARF5) and *BDL* the transcriptional repressor from Aux/IAA family (IAA12), both of which are involved in auxin response. Consistent with the similar early embryo phenotypes, *mp* and *bdl* interact genetically, and yeast two-hybrid studies also indicate that a physical protein interaction can occur. *AXR6* encodes the *Arabidopsis CULLIN1* (AtCUL1), a component of the SCF (*SKIP*, *CDC53/CULLIN*, and *F-box protein*) TIR1 complex. The SCF^{TIR1} is a complex with ubiquitin ligase function, which by binding and ubiquitination of Aux/IAA proteins (e.g. BDL) mediates their degradation. The involvement of BDL, MP, and AXR6 in the same patterning processes suggests that BDL and MP form a complex *in vivo* that prevents MP from activating target genes. In this scenario, auxin promotes interaction between BDL and SCF^{TIR1} complex, which ultimately leads to BDL degradation. Consequently, derepressed MP is able to mediate auxin-dependent gene expression and thereby initiate root formation.

On the other hand, the *gn* mutant, which also displays severe aberrations in apical-basal pattern, is defective in the guanine-nucleotide exchange factor on ADP-ribosylation factor G proteins (ARF-GEF). Endosomal membrane-associated GNOM ARF-GEF acts as an activator of ARF G proteins, which play a role in the recruitment of vesicle coats required for their budding and cargo selection. Here, the mechanistic connection to auxin signaling and transport was established through a role for GN in vesicle trafficking that mediates proper subcellular targeting of PIN auxin transport components.

Thus, the molecular analysis of embryo patterning mutants suggested a prominent role for the phytohormone *auxin* (indole-3-acetic acid, IAA) in the regulation of this process.

2.5.2.3 **Differential auxin distribution in embryonic axis formation.** Complementary evidence for the involvement of auxin in embryo development has been obtained through chemical manipulation of auxin homeostasis in excised *Brassica* embryos. The main breakthrough in understanding the role of auxin in embryo patterning was the discovery of dynamic *auxin gradients* during embryogenesis. Cellular distribution of auxin and its response was indirectly visualized using anti-IAA antibodies and an auxin-responsive reporter *DR5::GFP*. Immediately after the division of the zygote, auxin accumulates in the apical cell, which is being specified. During subsequent development, the maximum auxin activity persists in the proembryo. Approximately at the 32-cell stage, when the basal embryo pole is being specified, the gradient of auxin accumulation suddenly reverses and forms a new maximum in the uppermost suspensor cells, including the hypophysis. At later stages

of embryogenesis, additional auxin accumulation foci appear in the tips of the developing cotyledons. The next important question was, by what mechanism are these auxin gradients established and maintained. Conceptually, cellular auxin levels could be regulated by different levels of synthesis/degradation and conjugation/deconjugation or by intercellular transport.

Auxin is unique among plant hormones, being actively distributed within the plant by cell-to-cell movement. This movement is strictly directional (polar) and involves auxin influx and efflux carrier proteins. The direction of auxin flow is supposed to be determined by the asymmetric cellular localization of efflux carriers. The plant-specific PIN proteins have so far been the best-characterized candidates for facilitators of auxin efflux. Since both chemical and genetic (*gn* and *pin* mutants) inhibition of auxin transport interferes with the embryonic auxin gradients, it seems that polar auxin transport is a major determinant for establishing and maintaining auxin gradients. Furthermore, inhibition of auxin transport leads to severe embryo developmental defects, ranging from cup-shaped embryos with misspecified apical structures and a nonfunctional root pole, to ball-shaped embryos without any discernible apical–basal axis. These findings indicate that auxin transport–dependent auxin gradients are required for proper embryo development. Analysis of expression and localization of PIN auxin transport components finally completed the model, describing the role of PIN-dependent auxin distribution in the establishment of the embryonic apical–basal axis (Fig. 7c).

In the early stages, auxin is actively provided to the apical cell from the adjacent basal cell by the action of basal cell-specific, apically-localized PIN7. In subsequent stages, the cells of the suspensor continue to localize PIN7 on their apical side, while in the proembryo, another protein, PIN1, is produced without apparent polarity. But after the 32-cell stage, PIN1 becomes localized to the basal membranes of the provascular cells and PIN7 polarity in suspensor cells reverses, suggesting downward transport toward the region of the future root pole and out of the embryo. *PIN4* expression then starts at the basal pole of the embryo, supporting the action of both PIN1 and PIN7. As a result of these changes in auxin flow, the auxin gradient reverses, displaying its new maximum in the uppermost suspensor cell, which in response to auxin is specified to become the *hypophysis* – the founder of the future root meristem.

Thus, developmentally regulated changes in polarity of PIN proteins result in the redirection of auxin fluxes for local auxin accumulation, which is required first for specification of the apical and later the basal pole of the embryonic apical–basal axis. Interestingly, it seems that a similar mechanism utilizing PIN-dependent auxin distribution also operates in postembryonic development such as organogenesis. Regardless of the type of organ primordia, the new direction of PIN-mediated auxin transport determines the growth axis of the developing organ.

2.5.3 Interregional Communication During Seed Development

It seems obvious that seed development requires the coordination of embryo and endosperm development and therefore requires communication between these two regions. The available evidence for this communication relies

mostly on the analysis of mutant phenotypes in *Arabidopsis*. For example, mutants in two genes, *FERTILIZATION-INDEPENDENT ENDOSPERM* (*FIE*) and *FERTILIZATION INDEPENDENT SEED2* (*FIS2*) have similar phenotypes to the *Arabidopsis medea* (*mea* mutant). In the absence of double fertilization, continual divisions of polar nuclei are followed by cellularization, and overproliferation of the endosperm is accompanied by aberrant embryo development. Specifically, analysis of the *haiku* mutant confirmed that endosperm development plays a role in late embryo development. Further elegant studies using conditional expression of diphtheria toxin in different regions of developing seed allowed selective ablation of the endosperm. This leads to clear embryo and seed development defects demonstrating an important role for the endosperm in embryo development and confirming the communication between these seed regions. However, the molecular nature and mechanism of this communication remains unknown.

2.6 Seed and Fruit Formation

Double fertilization activates, in parallel with embryo and endosperm development inside the embryo sac, transformation of an ovule into a *seed* and transformation of the ovary into a *fruit*. In cases in which pollination and fertilization do not occur, flower abscission follows.

2.6.1 Seed and Fruit Maturation

Both seed and fruit formation include processes of growth and maturation (ripening). General changes during fruit ripening include (1) changes of color through chlorophyll degradation and carotenoid or flavonoid accumulation, (2) textural modifications caused by changes of cell wall structure and cell turgor, (3) qualitative as well as quantitative changes in sugars, acids, and other substances that affect flavor, aroma, and nutritional quality, and (4) increase of respiration and ethylene synthesis during ripening. Such an increase is typical only for the so-called climacteric fruits such as the fleshy fruits of tomato, apple, and banana. Ethylene production is not involved in ripening of nonclimacteric fruits in which exogenous ethylene can cause increased respiration while natural ripening is not promoted. Multigene families of ACC synthase and ACC oxidase control regulation of ethylene synthesis during climacteric ripening. Genes for both synthesis and degradation of proteins are activated during the ripening process.

2.6.2 Dormancy and Seed Germination

The period of seed maturation is rounded off by transition to a stage of reduced growth, which can be either *quiescence* or *dormancy*. Quiescent seeds can germinate in appropriate physiological conditions, while dormant seeds require additional hormonal and environmental regulation mechanisms for initiation of germination. Seed dormancy can represent a benefit either during embryo formation, when it prevents precocious germination, or as a regulator of seed germination in unfavorable conditions; otherwise, seed dormancy can be an inconvenient factor in agricultural crops, where rapid germination is required. Processes leading to seed dormancy are a part of the normal developmental pathway of seed formation. They include (1) gradual desiccation, (2) differentiation of the seed coat, (3) changes in gene transcription, and

(4) reduction of cellular metabolism. Regulation of these processes involves activation of the transcription of new genes. Some of them can shut off transcription of genes regulating cellular metabolism, while others may be involved in regulation of seed formation. The phytohormone abscisic acid (ABA) is involved in the regulation

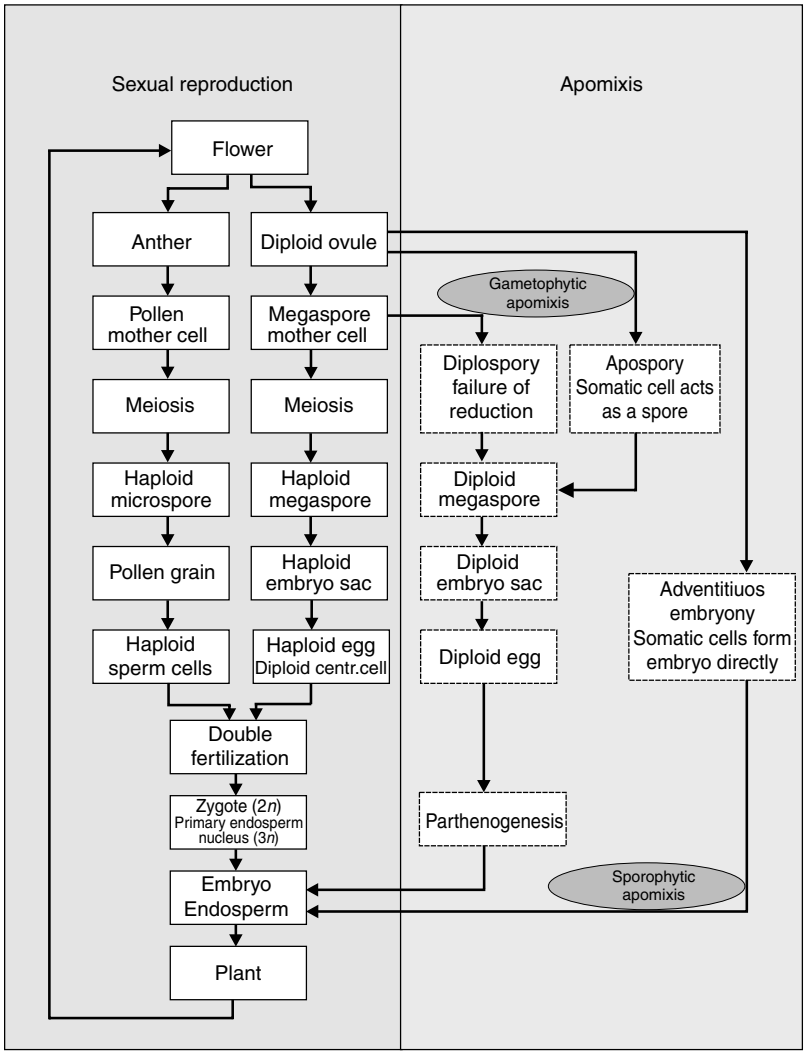


Fig. 8 Comparison of apomixis and sexual life cycle of flowering plants. Apomictic reproduction by seed occurs when the sexual life cycle is shortened. Sporophytic apomixis (adventitious embryony) occurs when the unreduced cells of the ovule directly give rise to an embryo. Gametophytic apomixis occurs by the formation of an unreduced megaspore either due to failure of megaspore mother cell reduction (diplospory) or by the formation of an unreduced megaspore from the somatic cells of a diploid ovule (apospory). (See color plate p. xxix).

of the onset and in maintenance of dormancy. ABA accumulation in seeds is low during early embryogenesis and then increases during storage-reserve biosynthesis and declines when the seed undergoes maturation. Lowering of water potential is the signal for ABA accumulation. The course of dormancy is regulated by differential gene activation. *LEA* genes encode proteins more abundant in mature embryos than in young or germinated embryos. Expression of *LEA* genes can be induced by ABA.

Overcoming seed dormancy can be achieved by various pretreatments like scarification, prolonged washing, and storage at low or high temperature enabling additional ripening of seeds, or exposure to light or dark conditions. Seed *germination* begins with events such as water uptake, resumption of metabolic activity, degradation of LEA proteins, production of new proteins, and mobilization of stored food reserves. Termination of seed germination is manifested by the elongation of the embryonic axis, which is completed by penetration of a root pole through the seed envelope. Information for synthesis of the first proteins that are essential for germination and root cell elongation comes from mRNA stored in the embryo during embryo development.

3 Apomixis

Apomixis is a naturally occurring process of asexual reproduction through seeds. It involves elimination of key developmental processes including meiosis and double fertilization. In nature, apomixis is widespread but infrequent: it occurs in 40 families of flowering plants, but only in about 400 species, which represents 1% of the species that make up those families. Apomixis is most frequent in *Poaceae*, *Asteraceae*, and *Rosaceae* families. Occurrence of various forms of apomixis in different angiosperm taxa can suggest that it has evolved independently many times. Classification of numerous mechanisms of apomixis into two main subgroups is based on the origin and further development of the unreduced cells (Fig. 8.). *Sporophytic apomixis*, also called *adventitious embryony*, is a process in which the embryo arises spontaneously directly from the cells of the nucellus or the integuments of the ovule. More common *gametophytic apomixis* occurs when the apomictic embryo arises from the cells of the unreduced megagametophyte. Gametophytic mechanisms are further divided according to the origin of the cells that give rise to the apomictic embryo. In *diplospory*, the MMC that failed in meiosis is the progenitor of unreduced embryo sac. *Apospory* in which the unreduced embryo sac arises from the somatic cells of the ovule is the most common mechanism of apomixis. Pollen of apomictic plants is often viable. Sometimes, development of both sexual and asexual seeds occurs in the same flower, although precocious apomictic embryo formation before flower opening or synthesis of complete cell wall around the unreduced egg cell can prevent fertilization in apomictic species. Apomixis as a mechanism for rapid generation and multiplication of desired genotypes through seeds is a very attractive idea for plant breeders. Artificial introduction of apomixis into crops as a reproductive alternative is the aim of many attempts as it could represent a unique opportunity to simplify breeding schemes and genetically perpetuate any desired heterozygous genotype.

Keywords

Bronchiolitis
Clinical pediatric respiratory illness manifested by wheezing, cough, and hypoxia.

Paramyxovirus
The virus family to which RSV belongs.

Pneumonia
Inflammatory infectious process of the lower airway and alveoli of lung.

Pneumovirus
The virus genus to which RSV belongs.

Respiratory Syncytial Virus
An RNA virus causing respiratory illness in humans.

RNA Virus
A virus whose genome is composed of RNA.

Respiratory syncytial virus (RSV), an enveloped single-stranded negative-sense RNA virus, is an important cause of serious respiratory tract illness in infants, older adults, and persons with underlying cardiopulmonary disease. Winter time epidemics occur annually in all parts of the world and account for significant morbidity and mortality. Immunity to infection is incomplete and reinfections are common, often associated with serious consequences especially in frail elderly persons and the severely immunocompromised. There is substantial experimental evidence that the clinical characteristics are primarily influenced by the nature of the innate and cellular immune responses to infection. Development of a successful vaccine requires an understanding of the relationship between protective and pathogenic immune responses.

1 Introduction and History

Human respiratory syncytial virus (RSV) was originally isolated in 1956 from a laboratory chimpanzee with respiratory symptoms and tentatively named *chimpanzee coryza agent*. The next winter, a similar virus was recovered from two infants hospitalized with respiratory symptoms and was renamed to reflect the giant syncytia that develop in cell culture. In the ensuing decade, RSV was proven to be the single most important cause of serious lower respiratory tract infection in infants and young children. Among this age group, it is estimated that in the United States >120 000 hospitalizations and ~235 deaths annually are attributable to pneumonia and bronchiolitis caused by RSV and a substantially greater number in developing countries. In addition, RSV infection in infancy has been causally associated with recurrent wheezing during childhood. Perhaps most vexing of all, immunity to RSV is incomplete and frequent reinfection occurs throughout life. In older age groups and those with underlying cardiopulmonary diseases, RSV probably accounts for at least 80 000 hospitalizations and 13 000 deaths each winter. Certain immunocompromised adults, such as bone marrow transplant recipients, are also at risk of severe RSV infection with high mortality rates.

Despite remaining a high priority target for vaccine development since its discovery, attempts at active immunoprophylaxis, spanning nearly 40 years, have proven unsuccessful. Parenterally administered inactivated whole virion, parenteral live virus, and intranasally administered live attenuated vaccines have each been evaluated and abandoned for various reasons. The first vaccine trial using a formalin-inactivated whole virus preparation produced in the 1960 s was disastrous. Not only did the vaccine fail to protect young infants, but it was associated with more severe illness in vaccinees who became infected during the subsequent RSV season with an 80% hospitalization rate among RSV-infected vaccinees. Animal studies have provided insight into the immune mechanisms underlying this vaccine-induced enhanced disease, although a full understanding may never be available. Shortly thereafter, a parenterally administered live virus preparation also failed to protect young children from infection, although enhanced disease was not noted. Interspersed with these trials, a series of intranasally administered live attenuated virus vaccines were tested and rejected because they were either overly attenuated, poorly immunogenic, or retained excessive virulence. More recently, recombinant live attenuated vaccine with specific genetic alterations have been tested in humans following initial studies in rodents and nonhuman primates. Perhaps with a better understanding of protective immunity, molecular virology, and disease pathogenesis we can improve on the earlier efforts that were largely based on empiric approaches successfully used with viruses such as polio and mumps. This chapter will review the molecular biology, epidemiology, and immunology of RSV infection to provide a framework for assessing this task.

2 Molecular Biology of RSV

2.1 Classification

Human RSV is an enveloped nonsegmented negative-sense RNA virus,

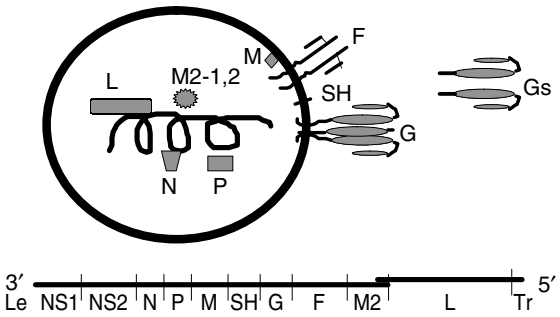

Fig. 1 Schematic structure of respiratory syncytial virus and genome organization.

classified within the genus *Pneumovirus* of the family *Paramyxoviridae*. Other closely related viruses include bovine and caprine RSV, the newly identified human metapneumovirus, turkey rhinotracheitis virus, and pneumonia virus of mice. The *paramyxoviridae* also include two other genera; *morbillivirus*, of which measles virus is the principal human pathogen, and *paramyxovirus*, containing the parainfluenza viruses of humans (PIV 1–4) and animals (Sendai virus) and mumps virus. All of these viruses share similarities of genomic organization, virion structure, and replication strategies, although RSV is distinguished by gene number and order and the absence of hemagglutinin and neuraminidase activity.

2.2 Physical Structure of RSV

By electron microscopy, RSV is a pleomorphic spherical or filamentous virus of variable diameter (80–350 nm) and length (up to 10 μm). Replication is cytoplasmic, and mature virus buds from the apical cell membrane of polarized respiratory epithelial cells. A significant proportion of viral particles remain cell associated, and analysis of purified virus is complicated by contamination with cellular material. Eight structural and three nonstructural proteins (NS1, NS2, and Gs) have been characterized in detail (Fig. 1). There are three transmembrane glycoproteins; F (fusion protein) and G (attachment protein) form trypsin sensitive 11–20 nm spikes projecting from the viral membrane, and trace amounts of a small hydrophobic protein (SH) whose function is unknown. Within the envelope, the tightly coiled helical ribonucleoprotein capsid contains genomic RNA (vRNA) encased in the viral nucleocapsid protein (N) and associated with the less abundant phosphoprotein (P), M2-1 and M2-2 proteins, and the polymerase (L) protein. The M protein is a membrane associated matrix protein and the M2-1 and M2-2 proteins, products of the M2 gene, are important in viral transcription and replication.

The virus is relatively labile under most conditions, with 99% of viral infectivity lost after 10 min at 55 °C, 48 h at 37 °C, and 2 weeks at 4 °C. Inactivation is retarded by addition of 1 M $MgSO_4$ (yielding a half-life of 12 weeks at 4 °C), rapid freezing in a dry ice-alcohol bath, and preservation at −70 °C with added glycerin or 25% sucrose. The virus has a density of 1.18 g cm^{-3} on sucrose gradients, a method commonly employed for purification.

2.3 Genomic and Messenger RNA

The single-stranded negative-sense genome contains 15 222 nucleotides (nt) and contains 10 genes flanked by noncoding leader (Le) and trailer (Tr) sequences in the following order: 3′ Le-NS1-NS2-N-P-M-SH-G-F-M2-L-Tr 5′ (Fig. 1). Messenger RNA is transcribed directly from vRNA, while synthesis of new vRNA requires a full-length positive-sense genomic template. The 44-nt leader and terminal portion of the 155-nt trailer sequence have a high degree of complementarity, a feature common to paramyxoviruses. The leader sequence is thought to promote encapsidation of the vRNA by N and serves as the sole promoter for both mRNA and the positive-sense replicative intermediate of vRNA.

Each gene begins with a highly conserved 9 nt gene-start signal (3′CCCCGUUUA) and ends with a semiconserved 12–13 nucleotide gene-stop sequence, comprised of a conserved 3′..UCAAU..5′ and a poly U_{4-7} tract with an intervening nonconserved 1–4 nt region. Nonconserved intergenic regions of 1–52 nt separate the genes. Each gene specifies a single monocistronic mRNA except for the M2 gene, which has two open reading frames that are transcribed into mRNA for the M2-1 and M2-2 proteins. In addition, a second initiation site in the transmembrane region of G allows for the production of Gs, a soluble secreted form of G protein. Transcription is initiated at a single 3′ polymerase entry site with sequential transcription of the downstream genes using a ''stop–start'' mechanism in which the polymerase must terminate transcription of the upstream gene before progressing across the intergenic sequence to initiate transcription of the subsequent gene. With each stop–start, there is inefficiency resulting in a decreasing gradient of transcription products in a polar fashion inversely related to the distance from the 3′ genome end. Thus, the largest amount of mRNA is noted for early genes (NS1, NS2, N) and the least for downstream ones (F, M2, L). The gene-stop sequence also regulates transcription efficiency at each gene junction. Single nucleotide changes to any of the three regions significantly alters transcription termination efficiency and amounts downstream gene mRNA.

2.4 Genetic and Antigenic Diversity among RSV Isolates (Strains)

Human RSV isolates are divided into two major groups, A and B, each with multiple subgroups based upon reactivity with monoclonal antibodies and confirmed by genetic sequence data. Monoclonal antibodies have identified antigenic differences both between RSV groups and within groups for several proteins, including F, G, P, and N with the greatest sequence divergence noted in the G protein. Genetic analysis reveals even greater heterogeneity among virus isolates (Table 1). The F, N, P, M2, NS1, and NS2 proteins are highly conserved (>78% nucleotide homology and >87% amino acid homology), as are the noncoding leader, trailer, and gene-start sequences. In contrast, the attachment protein G, followed by SH, have the greatest degree of genetic variability. Analysis of multiple isolates indicates that there is ~50% amino acid sequence variability between group A and B virus G genes, and as much as 20% within groups. Concordantly, there is low antigenic relatedness (~3–7%) between the G proteins of group A and B virus, determined by cross neutralization with G

Tab. 1 Genetic and amino acid homology between and within RSV groups.

specific polyclonal antisera or by EIA with postprimary infection human sera. A high proportion of the nucleotide changes resulting in amino acid substitutions occur in hypervariable regions that contain neutralizing epitopes and supports the notion that sequence changes may be the result of antibody mediated immune pressure. Detailed analysis of the evolution of G protein during the past 40 years indicates slowly accumulating (0.25% per year) amino acid substitutions. Variability in the G protein can be due to single nucleotide substitutions, frameshifts, and changes in location of termination codons.

2.5 Structure and Function of the RSV Proteins

2.5.1 Attachment Protein (G)

The G protein is the primary viral attachment protein, although replication competent viruses lacking the entire G gene have been described. G has several unusual features that distinguish it from the more common hemagglutinin-neuraminidase and hemagglutinin attachment proteins of other paramyxoviruses (Fig. 2). G is ~298 amino acids in length which predicts a 33 kDa size, although numerous carbohydrate side chains account for the final 90 kDa size. G is a type II envelope protein with a hydrophobic transmembrane region 38 residues from the amino terminus. Striking features include a high serine and threonine content (30.6%) that provide numerous acceptor sites (>70) for short O-linked carbohydrate side chains. There are also four predicted N-linked glycosylation sites. This glycosylation pattern, rare for viral glycoproteins, is characteristic of mucinous proteins secreted by respiratory epithelium. A high proline content (13% in the ectodomain)

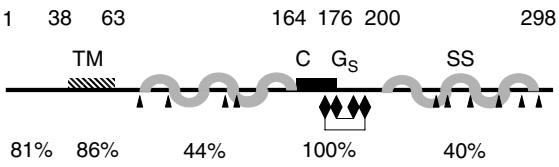

Fig. 2 Schematic representation of the RSV G protein. The amino acid numbers are indicated at the top, and the degree of homology between group A and B viruses for each of the regions are shown at the bottom. The transmembrane region is indicated by the hatched bar, and the central conserved region of 13 amino acids by the black bar. The conserved cysteine noose (CX3C motif) is represented by diamonds with intermolecular disulfide bonds by the lines. The mucin-like O-linked glycosylation sites are represented by the gray lines. Potential N-linked sites are indicated by the triangles.

may contribute to a nonglobular structure. The intracytoplasmic and transmembrane regions are well conserved (84%) between group A and B strains, while the ectodomain contains variable and hypervariable regions that flank a conserved 13 aa cysteine rich region (aa 163–176). This later region has structural and functional analogy to a cysteine rich motif found in the CX3C chemokine fractalkine (see Sect. 4.2). During translation, the 33 kDa G protein undergoes stepwise modification by the addition of N-linked complex high mannose carbohydrate side chains, bringing the molecular weight to 45 kDa, followed by the addition of O-linked carbohydrate yielding the mature 90-kDa protein. The carbohydrate residues play important roles in the synthesis of G, viral infectivity, and immunogenicity. Transport of G to the cell surface is diminished only when both N- and O-linked sugars are absent and enzymatic removal of carbohydrate from purified virus reduces infectivity by 98%. Finally, many Mabs react only with fully glycosylated forms of G, although neutralizing and protective Mabs, which react with the nonglycosylated 33 kDa G protein, have been described. Genetic analysis of Mab escape mutants and reactivity of Mabs and human serum with synthetic peptides have identified several discrete neutralizing sites on G, most of which are group or subgroup specific, although at least one neutralizing site in the conserved cysteine rich area has been described.

In addition to the membrane anchored G found in virions, a truncated G is secreted from infected cells (Gs), the result of translation starting at Met48 in the transmembrane region. The role of Gs in viral growth and disease pathogenesis is unknown, although it has been shown to bind the fractalkine (CX3CR) receptor and have chemokine-like properties (see Sect. 4.2).

Although G is the principal RSV attachment protein and binds to cell membrane heparin-like glycosaminoglycans and to CX3CR, naturally occurring and engineered replication competent viruses lacking the G gene have been described. F protein alone apparently can provide the cell attachment function. However, these deletant viruses replicate more slowly and to lower titer than virus expressing all three surface glycoproteins.

2.5.2 Fusion Protein (F)

The RSV F protein is a type I transmembrane glycoprotein that, in its mature proteolytically cleaved trimeric form, is responsible for pH-independent fusion of the viral envelope with the cell plasma membrane and facilitates cell entry of the nucleocapsid complex. During replication, F induces cell-to-cell fusion that

produces the characteristic syncytia seen in cell culture, and facilitates spread of virus to adjacent cells. The importance of cell–cell spread in human infection is unknown although microscopic examination of lungs from infants who succumb to RSV have demonstrable giant cell formation. F is 574 amino acids in length and has a calculated molecular weight of 63 kDa (Fig. 3). Three of five potential N-linked carbohydrate acceptor sites are used, which increases the molecular weight to 70 kDa. Similar to the fusion proteins of other paramyxoviruses, F is synthesized as an inactive precursor and posttranslationally modified in the Golgi by simultaneous addition of N-linked complex carbohydrate side chains (Fo) and cleaved by furin-like proteases into disulfide linked 48-kDa (F_1) and 23-kDa (F_2) subunits to form an active fusion protein. Upon cleavage, a long hydrophobic region on the amino terminus of F_1 is exposed, which, by analogy to other paramyxoviruses, is probably important in membrane fusion. Interestingly, the F_2 fragment, and not the G protein, determines host cell tropism. Like the G protein, the F protein binds to cell-associated heparin sulfate and may contribute up to 25% of the virus-cell binding. Two heptad repeats, at either end of the F_1 fragment, are important in fusion activity, and participate in secondary and tertiary structure of the final fusion permissive trimeric F protein that has a coiled coil structure. Although cells infected with recombinant vectors expressing F protein alone form syncytia, coexpression of G and SH are required for maximal fusogenic activity. The F protein also interacts with RhoA, a surface expressed cellular signaling protein associated with many cellular functions relevant to RSV pathogenesis.

The F protein contains major conserved neutralizing epitopes as defined by Mab binding studies and analysis of neutralization escape mutants. Both fusion-inhibiting and nonfusion-inhibiting neutralizing sites have been described, most of which are conserved in group A and B RSV isolates. Fusion-inhibiting neutralizing Mabs provide maximal protection in passive protection studies in rodents and one of these Mabs has been humanized (palivizumab; Synagis®) and licensed for prophylactic administration to high-risk infants. The binding sites of neutralizing Mabs have been mapped to regions on F by analysis of antibody binding to synthetic peptides, trypsin digest fragments of F_1, or genetically cloned fragments of F, as well as by sequence analysis of neutralization escape mutants. The majority bind to the N-terminal portion of F_1, between amino acids 200–230 or 250–290. At least one of the neutralizing, fusion-inhibiting Mabs binds to amino acids 283–315. In addition to B-cell epitopes, T-helper cell

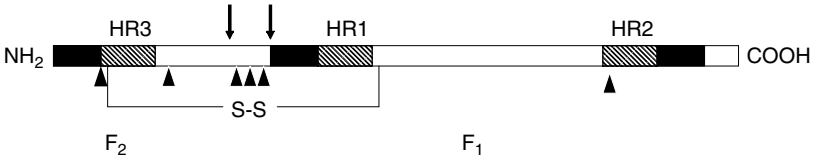

Fig. 3 Schematic representation of RSV fusion protein F. The signal peptide, cleavage activation region and transmembrane regions are shown in dark bars. The three heptad repeats are identified by hatched bars. Triangles indicate potential N-linked glycosylation sites, and the arrows indicate furin-like protease cleavage sites. The disulfide linkage of F_1 and F_2 fragments is indicated.

epitopes map to the F_1 fragment between amino acids 233–278 and 328–355. F also contains cytotoxic T-cells (CTL) epitopes although they are not well defined.

2.5.3 Small Hydrophobic (SH) Protein

The smallest of the RSV transmembrane proteins, SH, is analogous to a similar protein found in some paramyxoviruses. It is of unknown function, but may be important for efficient fusion activity of the F protein. The SH gene sequence indicates a protein of 64 amino acids, with a predicted size of 7.5 kDa. Multiple forms of SH, including 13–15 and 21–40 kDa molecules, are abundantly present in infected cells although only small amounts are found in purified virions. SH is characterized by a hydrophobic membrane spanning region from residue 14–42, an external C-terminus, and two potential glycosylation sites. Neutralizing epitopes have not been described; however, T- and B-cell epitopes have been identified. Genetically engineered RSV constructs lacking the SH gene (RSVΔSH) are fully replication competent.

2.5.4 Matrix Protein (M)

The RSV matrix protein is loosely associated with the inner surface of the viral membrane and by analogy, to other paramyxoviruses, which is important in assembly of viral proteins into budding virions at the cell membrane. M is 256 amino acids in length, has a 25 amino acid hydrophobic region near the C-terminus presumably for membrane interaction, and is phosphorylated.

2.5.5 Nucleocapsid Protein (N), Phosphoprotein (P), Polymerase (L), and the M2 Proteins (M2-1, M2-2)

The vRNA is encapsidated by the 44 kDa N protein, a requirement for transcription and genomic replication. The 32-kDa phosphoprotein (P) and the polymerase (L) comprise the RNA-dependent RNA polymerase, which directs transcription and vRNA replication. Transcriptional activity of the nucleocapsid complex peaks at 14 h postinfection and is severely restricted by 30 h when vRNA replication begins. The cytoskeletal protein actin is also required for transcription, since actin-specific antibody is inhibitory *in vitro*. Phosphorylation of P by cellular casein kinase II at a conserved serine residue (Ser^{237}) is critical for efficient transcription since wild-type unphosphorylated P or mutant P with an amino acid substitution at residue 237 have minimal transcriptional activity. Binding of P to the encapsidated vRNA, however, is not dependent upon Phosphorylation since mutant P competes with wild-type P binding.

The RSV L gene comprises 43% of the vRNA and encodes a protein of 2165 amino acids with a molecular weight of 250 kDa. The L nucleotide sequence defines four polymerase motifs common to other paramyxovirus polymerases. One conserved region contains an ATP-binding motif required for protein kinase activity. *In vitro* experiments have defined the optimum molar ratio of the N, P, and L proteins for transcription at 12 : 5 : 1. Notably, many of the nucleotide changes associated with temperature sensitivity during virus growth have been localized to the L gene.

The M2 gene encodes two products, M2-1 and M2-2, that are important in viral replication. M2-1, a product of the first M2 open reading frame, is an antitermination protein that enhances transcriptional processivity. Early unsuccessful attempts to generate recombinant virus with cDNA and plasmids expressing N, P, and L yielded incomplete mRNAs. The addition

of an M2-1 expressing plasmid allowed complete transcription of mRNA and production of recombinant virus. The 90 aa M2-2 protein functions as a regulatory factor involved in the balance between transcription and RNA replication, favoring the latter by way of a positive-sense vRNA intermediate.

2.5.6 Nonstructural Proteins (NS1 and NS2)

Unique among paramyxoviruses, RSV has two nonstructural proteins, which are synthesized in abundance due to the 3′ promoter proximal location of their corresponding genes. They function as antagonists of cellular interferons (IFN-α and -β), which are induced by RSV in respiratory epithelial cells as part of the innate immune response to infection (see Sect. 4.2). Recombinant viruses lacking these genes grow poorly in cells capable of interferon synthesis, and are attenuated in animal models of RSV.

3 Clinical Disease and Epidemiology of RSV Infection

RSV causes annual epidemics from late fall through early spring, and has been found in every locale in which it is sought. Overall, RSV accounts for ~250 000 total hospitalizations and ~10–14 000 deaths in all age groups annually in the United States. The virus is uncommon during the summer months except in tropical climates, where it coincides with the rainy season. RSV is the dominant cause of serious respiratory tract infection in the young, and accounts for nearly half of all pneumonia, 75 to 90% of bronchiolitis cases, and 10% of the group that requires hospitalization in the first year of life. During their first winter, 70% of infants are infected with the remainder infected the following season. Although most infants under a year of age have mild upper or lower respiratory tract symptoms, 1 to 5% are hospitalized depending on the presence of underlying medical conditions. The mean age at hospitalization is 2 to 3 months, a time when transplacentally derived antibody levels would have fallen to approximately one-tenth of those at birth. Importantly, infants appear to be spared serious infection in the first few weeks of life when antibody levels are highest. Risk factors for severe disease are present in approximately 25 to 50% of all hospitalized infants and include premature birth (<36 weeks gestation), congenital cardiopulmonary disease (with mortality rates of 37%), bronchopulmonary dysplasia, cystic fibrosis, congenital neurologic defects, and immunodeficiency states.

RSV is transmitted principally by large particle fomites, rather than by small particle aerosol-like influenza, with an incubation period of 2 to 5 days before the onset of rhinnorhea, cough, and fever. Lower respiratory symptoms of wheezing, tachypnea, and hypoxia will develop in approximately 30% of infants with first infections. It is estimated that >100 000 hospitalizations and ~250 deaths occur annually in the United States, although worldwide estimates are substantially greater, especially in underdeveloped and developing countries.

Reinfections occur throughout life, underscoring the imperfect immunity induced by natural infection. In the day care setting, three quarters of exposed, previously infected infants become reinfected. Generally, repeat infection is less severe than primary infection, and children above age three typically manifest mild upper respiratory tract symptoms. Adults are also at risk for reinfection and

47% of parents become infected when the virus is introduced into the home. In healthy working adults, illness is generally mild to moderate in severity, although lower respiratory tract signs and symptoms develop in 26% and 38% miss work. Among healthy elderly persons >65 years of age, 32% will seek medical attention during RSV infection. Overall, attack rates are ~5% in adult populations. In certain high-risk adult populations, RSV reinfections can cause severe illness. Nosocomial or community-acquired infection in bone marrow transplant recipients progresses to pneumonia in half of infected persons with 30 to 78% mortality. Residents of long-term care facilities or adults of any age with underlying cardiopulmonary disease may also become seriously ill with pneumonia and bronchitis. This age group represents an expanding population that may benefit from vaccination against RSV. Longitudinal studies in Rochester, New York, noted that RSV was associated with wintertime hospitalization of high-risk or elderly persons for acute cardiopulmonary symptoms and is nearly as frequent as influenza A virus infection (9.6 vs 10.4%, respectively). Overall, RSV probably accounts for >150 000 hospitalizations and ~14 000 deaths annually in elderly and high-risk adults in the United States.

During epidemics, virus strains representing both group A and B can be recovered. During a 15-year period (1974–1990) in Rochester, New York, group A viruses accounted for 71% of isolates overall, and only in four winters did group B isolates dominate. In contrast, during an eight-year period (1982–1990) in Caen, France, group B dominated four years and, overall, accounted for 64% of the isolates. The ratio of A to B viruses from 14 separate cities representing all regions of the United States during two consecutive winters varied considerably, thus suggesting that outbreaks of RSV are local in nature rather than national or global. In addition, there is regional and temporal variations in the circulation of viral groups, and subgroups. The clinical importance of antigenic variation on disease severity or in immunity has not been conclusively demonstrated, but is considered by many investigators to be relevant. Following primary infection, the antibody response to G is group specific and even subgroup specific. In addition, analysis of repeat infections in two small studies concluded that homotypic immunity may influence the RSV group responsible for secondary infection. Although not definitively proven, it is thought that the G protein antigenic changes are the results of antibody mediated immune pressure.

4 Immunology of RSV Infection

Although immunity is clearly incomplete, prior infections do reduce the frequency and severity of subsequent infection. Notably, there is substantial evidence, primarily from animal studies with inference to humans, that severity of infection and disease manifestations of RSV, in large part, are a result of the immune responses to the virus.

4.1 Transplacentally Acquired Maternal Antibody

Although the effect of passively acquired neutralizing antibody is limited owing to its rapid decline, most studies demonstrate reduced infection rates and severity of primary infection with higher levels

of antibody. Animal experiments support these conclusions. More definitively, prophylactic administration of high-titer RSV gammaglobulin or F protein specific monoclonal antibody to high-risk infants provides benefit. In these trials, severity of illness, but not infection rates, were reduced by half in treated infants. In experimental animals, protection is directly related to the serum neutralizing titer, with nearly complete suppression of virus growth at titers exceeding 1 : 380 dilution of serum. Murine monoclonal antibodies to either F or G protein are protective in animal models, in contrast to antibodies to internal viral proteins (N, P, M) (Table 2). Antibody dependent cell-mediated cytotoxicity and complement are not necessary for protection since F(ab_2) fragments can also inhibit RSV replication *in vivo*.

4.2 Innate Immunity

The earliest immune response to RSV involves nonadaptive innate immune mechanisms. Immediately following virus exposure, cells express and secrete a large number of proinflammatory and immunomodulatory cytokines and chemokines. Some have direct antiviral and inflammatory effects, while others also affect the subsequent T-cell adaptive immune response. Substances induced from upper and lower respiratory tract epithelial cells *in vitro* include the cytokines interleukin (IL)-1, tumor necrosis factor (TNF)-α, and IL-6, the antiviral proteins IFN-α and -β, the CXC chemokine IL-8 (neutrophil chemoattractant), the CC chemokines RANTES, macrophage inflammatory protein (MIP)-1α, macrophage chemoattractant protein (MCP)-1, and the CX3C chemokine fractalkine. Additionally, intracellular adhesion molecules, major histocompatibility complex class I antigens and antigen transporter (TAP)-1 are also induced in infected cells. Some responses are triggered by the interaction of RSV with Toll-like receptor (TLR)-4 present on cells. The CD14-TLR-4 complex, a member of a family of proteins structurally related to Drosophila Toll proteins, directly interacts with the RSV F protein with subsequent expression of proinflammatory cytokines. In addition, it has been shown that RSV infection is associated with stimulation of natural killer (NK) cells, which also plays a role in the adaptive immune response.

Both RSV G protein or Gs bind directly to the fractalkine receptor (CX3CR) present on immune cells and, similar

Tab. 2 Immune responses to RSV.

Protein	*Antibody response to natural infection*	*CTL epitopes*	
		Mouse	*Human*
F	Neutralizing, fusion inhibiting	+	+
G	Neutralizing	−	−
SH	Nonneutralizing	−	+
N	Nonneutralizing	+	++
P	Nonneutralizing	+	+
M	Nonneutralizing	−	+
M2	Nonneutralizing	++	+

to fractalkine, can act as a chemoattractant. However, G also competitively blocks fractalkine binding to CX3CR, and thus the net effect on immune response is unclear. RSV also directly induces secretion of the tachykinin neuropeptide substance P (SP), a product of efferent neurons, dendritic cells, and lymphocytes. SP may exacerbate inflammation by mediating vasodilatation. *In vivo* studies in mice demonstrate that inhibition of SP reduces pulmonary inflammatory infiltrates during RSV infection. A similar role of SP in humans has not been confirmed.

4.3 Mucosal Immune Mechanisms

One of the earliest adaptive immune response to infection is the appearance of RSV-specific secretory IgA in nasal secretions, which coincides with disappearance of virus. In experimental animals, the IgA response to F and G proteins is relatively brief and the protective capacity and durability of IgA in humans is unknown. Some but not all adult challenge studies indicate that nasal wash neutralizing capacity correlates with resistance to infection. Similarly, the ability to infect infants and children with live attenuated viruses is not consistently correlated to nasal IgA. Possibly the greatest indictment of the protective capacity of nasal IgA is that healthy adults are readily infected experimentally just weeks after natural infection. In animal experiments, nasal virus replication is inhibited to a greater extent by local secretory IgA than serum IgG, although IgA-mediated immunity is brief (<8 months), in contrast to more durable pulmonary immunity from serum IgG (>18 months). Animal studies also suggest that T-cell immunity, especially $CD8^+$ cells, play a role in mucosal immunity.

4.4 Humoral Immunity

The infant's humoral response to primary and repeat infections has been extensively investigated with most attention given to anti-F, anti-G, and neutralizing antibody responses. Newly synthesized IgG is detected 14 days after primary infection, peaks at 1 to 2 months, and then slowly declines sometimes reaching undetectable levels by one year. Infants above the age of 8 months are more likely to have responses to F (100%) or G (78%) than younger infants (62 and 48%, respectively), perhaps due to the suppressive effects of preexisting maternally derived antibody and immunological immaturity. Not surprisingly, the antibody response to G is group specific, consistent with the strain-specific amino acid differences, although moderate cross reactivity to the heterologous G is noted when the infecting strain is of group A. Analysis of antibody response using peptides representing subgroup specific hypervariable regions also demonstrates subgroup specific responses. Although the F response is highly cross-reactive, postinfectious neutralizing capacity is greatest against the homologous virus group with primary infection. Possibly of importance in vaccine development, group A RSV infection induces better cross neutralization than group B infection. The IgG subclass response to F and G following primary infection is predominantly IgG_1 and IgG_3, subclasses usually induced by protein antigens. This was unexpected since carbohydrate antigens (such as the heavily glycosylated G protein) usually stimulate IgG_2. Following three or more infections, IgG levels of F and G are boosted, reaching adult levels after the third infection. Interestingly, young adults with repeat infection have

rather weak antibody responses despite significant symptoms. In contrast, elderly adults with RSV infection have very strong EIA and neutralizing serum antibody responses to infection, exceeding those of young adults. The mechanism behind this difference is unknown. Serologic studies in elderly adults have confirmed that both severity and illness rates are less in persons with higher levels of neutralizing antibody.

The frequent presence of wheezing during primary RSV infection prompted measurement of RSV-specific IgE in serum and nasal secretions. Wheezing infants are more likely to have virus-specific IgE, histamine, and eosinophilic cationic protein in nasal secretions. The relationship of RSV-specific IgE in nasal secretions during acute RSV to future episodes of wheezing or development of asthma is uncertain although several studies implicate RSV IgE with increased wheezing during the first 4 to 5 years of life. In addition, bronchoconstrictive leukotrienes are released by macrophages infected *in vitro* in the presence of RSV IgG, a finding which strengthens the notion that symptoms are related to the host immune response. Interestingly, RSV infection in HIV-infected infants, develop diffuse interstitial pneumonia rather than bronchiolitis.

4.5 Cellular Immunity

Cell-mediated immunity is the primary mechanism for recovery from most virus infections, and there is data which suggests that the specific nature of the T-cell response determines the clinical manifestations of infection. Furthermore, the T-cell response to various RSV vaccine strategies appears to dictate the clinical outcome of subsequent RSV exposure. In general, replicating virus stimulates T-helper cells ($CD4^+$) with a Th_1 cytokine profile (interferon-γ) in contrast to inactivated or nonreplicating antigens that stimulate a Th_2 cytokine profile (IL-4, IL-5, IL-13). Th_1 responses are associated with processing of replicating antigen in context with class I histocompatibility proteins resulting in production of neutralizing IgG_{2a} (mouse system) or IgG_1 (human system) antibody and $CD8^+$ CTL. In contrast, Th_2 responses develop when nonreplicating antigens are processed in association with class II histocompatibility proteins resulting in synthesis of IgG_1 and IgE (mouse system) or IgG_4 and IgE (human system) without CTL induction.

In the murine model, clearance of RSV is unaffected by B-cell deficiency, whereas T-cell depletion results in persistent virus shedding. Virus eradication correlates with induction of $CD4^+$ cells with Th_1 cytokine characteristics resulting in the expected IgG_{2a} and CTL. $CD8^+$ CTL are lytic for target cells infected with either group A and B virus and are detected in the lungs of mice on day 7 postchallenge when clearance of virus occurs. Recent evidence also suggests that RSV may persist in the lungs of infected mice, as evidenced by detection of vRNA for up to 3 months following challenge. The significance of this is unknown but provocative data from patients with chronic obstructive pulmonary disease suggests that persistence may also occur in humans.

Infusions of RSV-specific $CD8^+$ CTL lines or clones clears virus in normal or persistently infected immunodeficient mice. Using target cells infected with recombinant vaccinia viruses (rvv) expressing RSV proteins has identified the N, F, and M2 proteins and possibly P as CTL targets in the mouse system. Mice

immunized with rvv-N or rvv-M2 are protected from RSV challenge, but protection wanes by day 28. Immunization with rvv-M2 confers protection from both group A and B challenge, perhaps due to a specific CTL epitope that has been mapped to a sequence (amino acids 82–90) conserved between both major RSV groups (see Sect. 2.5.4). Immunization of mice with a DNA vaccine expressing this short peptide induces high-level resistance to virus challenge, which can persist for several months.

Important for vaccine development, the priming immunization significantly alters T-helper cytokine mRNA expression in the lungs of mice when they are subsequently challenged with virus. Live virus immunization stimulates a Th_1 pattern and following virus challenge, replication is restricted and the pulmonary infiltrate is mild with predominantly PMNs and lymphocytes. In contrast, intramuscular (im) injection of FI-RSV or purified F protein (PFP) induces a Th_2 pattern with more extensive infiltration of lymphocytes and eosoinophils. Notably, vaccination with a live vector expressing F induces a Th_1 response similar to live virus. In contrast, immunization with purified G protein, rvv-G, or rvv-Gs all induce a Th_2 cytokine profile without CTL, uses the $V\beta14^+$ T-cell receptor in processing of G, and the pulmonary infiltrate following challenge is predominately eosinophils in nature. Although the response induced by G is similar to FI-RSV, the G protein is not a requirement for FI-RSV induced eosinophilia. These findings are analogous to the eosinophilic infiltrates seen in infants who died of RSV infection in the earlier FI-RSV vaccine trials.

The respective roles of $CD4^+$ and $CD8^+$ T cells in virus clearance has been investigated by passive transfer or depletion of specific cell types prior to virus challenge. Depletion of either $CD4^+$ or $CD8^+$ cells results in higher and slightly prolonged virus shedding, while depletion of both subsets results in prolonged, high titered virus shedding. Passive transfer of either RSV-specific $CD4^+$ or $CD8^+$ cells reduces virus lung growth, but a dose dependent increase in pulmonary pathology, characterized by lung hemorrhage and polymorphonuclear infiltration is noted when large numbers of $CD8^+$ T cells are infused, consistent with the concept that both $CD4^+$ and $CD8^+$ cells contribute in individual ways to the inflammatory process. The mechanism employed by $CD8^+$ CTL may also influence outcome, as perforin mediated cytotoxicity is more efficient and targeted than Fas ligand mediated killing in which uninfected cells are also lysed. This is the evidence that IL-4 (a type 2 cytokine) can stimulate the latter response with resultant nonspecific cell death and delayed virus clearance. The clinical manifestations of illness in the murine model (ruffled fur, weight loss) is also linked to TNF-α secretion. Overall, the results from the mouse model reinforces the concept that immune responses to RSV influence clinical illness.

Considerably less is known about the cell-mediated immune response in humans, especially infants. There is *in vitro* evidence of impaired lymphocyte proliferation responses to RSV; specifically, stimulation of peripheral blood mononuclear cells *in vitro* with live virus suppresses lymphocyte proliferation in contrast to inactivated RSV or live influenza virus. It has been speculated that this may contribute to suboptimal immune responses and contribute to reinfection. Technical limitations have impeded study of the infant's CTL response. Nevertheless, 4 of 22

infants, ages 9 days to 11 months hospitalized with RSV bronchiolitis, had measurable CTL activity in peripheral blood mononuclear cells within the first week of infection. In another study, 5 of 13 infants under 6 months of age and 8 of 12 infants over 6 months of age developed a CTL response, generally within the first week after infection, which rapidly dissipates in the ensuing months. In another study of RSV-infected hospitalized infants, both Th_1 and Th_2 cytokine profiles could be detected by flow cytometry. The specific antigens involved in the human CTL response has only been examined in adults; N, SH, F, M, M2, and NS1 have been identified as CTL targets (Table 2). Peripheral blood mononuclear cells from adults and infants produce both Th_1 cytokines (γ-interferon) and Th_2 cytokines (IL-4, IL-5) when stimulated *in vitro*.

4.6 Disease Pathogenesis

The clinical manifestations of RSV infection and severity of disease are multifactorial. There is evidence that severity can be related to the RSV group or subgroup, with several reports suggesting that group A virus infections are more severe. However, the primary contributor to the inflammatory response and subsequent clinical manifestations are thought to be immune responses to the virus, attributable to specific RSV proteins. The innate and humoral immune responses have also been implicated in disease severity in either animal models or in humans. Host genetic variability may also contribute substantially to disease manifestations. Several investigators have analyzed cytokine gene polymorphism in infants with RSV infection and found mutations in IL-4, IL-4 receptor, IL-6, IL-9, IL-10, and TNF-α genes to be associated with more severe disease. In addition, genetic variability in Toll-like receptor-4 (TLR4) also has been identified as a factor that influences disease severity. Thus, it appears that multiple genetic factors influence the innate and adaptive immune responses to RSV infection and influence clinical severity.

5 Prior RSV Vaccine Trials

Four major approaches to RSV vaccination have been assessed in infants or adults: (1) parenterally administered inactivated whole virus, (2) intranasally administered live attenuated viruses, (3) parenterally administered live virus, and (4) parenterally administered subunit immunization.

In 1969, a large multicenter field trial of a formalin-inactivated whole virion vaccine (FI-RSV) in infants was published. The results of this study have had profound effects on subsequent RSV vaccine research and development. The vaccine virus (Bernett strain; group A virus) was grown in vervet monkey kidney cells, formalin inactivated and concentrated by centrifugation and adsorption to alum. Children, ages 3 months to 9 years, received 1 to3 immunizations over 3 months followed by careful surveillance. The humoral immune response, measured by an insensitive complement fixation assay and by neutralization titers, appeared satisfactory. In the ensuing winter, RSV attack rates in controls and vaccinees were similar; however, illness was consistently more severe among recipients of the RSV vaccine compared to unvaccinated controls or controls immunized with a similarly prepared trivalent parainfluenza vaccine. The youngest infants who were RSV naïve, were most adversely affected, although

children 12 to 24 months of age who may have already experienced an RSV infection, also had more severe illness. The clinical manifestations were indistinguishable from a typical RSV illness, but lower respiratory tract involvement was considerably more common (69 vs 9%), and hospitalization was 5 to 16 times more frequent among vaccine recipients. Peripheral eosinophilia was reported in 56% of RSV vaccinees compared to 11% of controls at one of the centers, although not at another. The adverse outcome, since designated as vaccine-associated enhanced RSV disease, has been likened to the atypical measles syndrome, which followed use of a similarly prepared formalin-inactivated measles virus vaccine. Two decades later, stored serum from these infants was found to contain binding antibody to F and G, which lacked functional activity in virus neutralization and fusion inhibition assays.

The pathogenesis of enhanced RSV disease associated with the FI-RSV vaccine has been meticulously scrutinized in various animal models, with the hope that the safety of future vaccines can be better predicted. Cotton rats immunized with original FI-RSV vaccine (lot 100) and challenged with live RSV develop more peribronchiolar lymphocytic and alveolar neutrophilic infiltration than controls immunized with im or intranasal live virus. Similar to the clinical trials, binding antibody to F and G proteins were induced, but neutralizing and fusion-inhibiting activity were diminished. Passive transfer of antibody from FI-RSV immunized mice did not reproduce the findings; thus, antibody alone is insufficient to cause enhanced disease.

As noted earlier, FI-RSV induces a Th_2 cytokine profile from $CD4^+$ T cells without demonstrable CTL activity that is associated with an eosinophilic pulmonary infiltrate. Depletion of $CD4^+$ cells prior to virus challenge of FI-RSV immunized mice reduces pulmonary infiltrates to a greater extent than $CD8^+$ depletion. Furthermore, FI-RSV induced histologic changes are diminished by *in vivo* depletion of IL-4 and IL-10 (Th_2 cytokines) but not by depletion of γ-interferon or IL-2 (Th_1 cytokines). These results have led to the suggestion that a Th_1 $CD4^+$ response with CTL induction is the desired result of an RSV vaccine, while a Th_2 response, in which CTL is lacking, may predispose vaccine recipients to enhanced disease.

Concurrent with the FI-RSV trials, live attenuated vaccines were sought by adapting virus to preferentially grow in the cooler nasal tissues rather than in the warmer lower respiratory tract by repeated passage at low temperature or by randomly inducing genetic mutations and searching for temperature-sensitive (*ts*) virus. The first such viruses, reported in 1968, were cold-passaged (*cp*) variants of the A2 strain. Viruses adapted to 34 and 28 °C successfully infected a high proportion of adult volunteers, but retained virulence. Further attenuation by repeated passage at 26 °C produced a candidate that was less infectious (8 of 45 challenged adults) and less virulent, but when tested in children, significant upper respiratory tract illness developed in three who had not been previously infected with RSV. Next, temperature-sensitive (*ts*) mutants, produced by growing A2 strain in 5-fluourouracil were tested. One mutant, identified as *ts*-1, replicated exclusively below 38 °C in tissue culture and was restricted to nasal tissues in hamsters. Initial trials in 9 adults found that although only 3 shed virus or had a serologic response, 6 of 7 who were challenged with wild-type A2 virus were protected. In children,

this vaccine was highly infectious (34 of 39 inoculated) and immunogenic (21 of 39 humoral responses and 31 of 39 nasal antibody responses), but nonimmune infants again developed upper respiratory illness. Equally disturbing, reversion to wild-type growth patterns was found. A 100-fold dose reduction eliminated symptoms but revertant virus was again recovered and protective efficacy from natural RSV was not discernible. Further alteration of *ts*-1 by nitrosoguanidine treatment resulted in overattenuation. Another mutant (*ts*-2) with deficient syncytia formation was poorly infectious and also had reversion.

The final early vaccine to undergo field testing was a subcutaneously administered live RSV preparation derived from a clinical isolate. Animal studies provided experimental evidence of both upper and lower respiratory tract protection. Following pilot studies in over 400 infants and children in whom immunogenicity and safety profiles were favorable, a placebo controlled efficacy study was performed in 510 infants above age 6 months. Serologic status and age at time of vaccination appeared to determine immunogenicity. Overall, 68% of seronegative infants responded in contrast to only 16% of seropositive infants. Seronegative infants >12 months of age had the highest response rates (90%). Follow-up during the two subsequent RSV seasons documented neither protection nor enhanced illness attributable to vaccination, regardless of the serologic response to immunization.

More recent efforts to develop live attenuated vaccines have utilized reverse genetics to construct and selectively tailor virus vaccine candidates. Genetic analysis of the above noted *ts* and *ca* mutants allowed investigators to combine growth limiting mutations in different genes in order to further attenuate the virus and inhibit reversion. Several have been tested in adults, older children, and infants, but the same difficulties of overattenuation and poor immunogenicity, or excessive virulence have been noted. The most promising of these newer vaccine candidates, known as *cpts* 248/404 (designating mutations in the N, F M2, and L genes), was judged to be only minimally virulent in the youngest of infants, and preliminary evidence suggested it may be protective.

In addition to live attenuated viruses, subunit vaccines, which often rely on the common F antigen have been assessed in specific populations. These vaccines are generally not considered to be viable candidates for RSV naïve infants, due to their propensity to induce Th2 responses in mice, with the associated inflammatory infiltrates upon virus challenge. One such vaccine of PFP adsorbed to alum has been studied in phase I and II trials in older high-risk children with cystic fibrosis and in healthy elderly and frail nursing home subjects. Although safe and moderately immunogenic when administered intramuscularly, further studies have not been carried out. PFP has also been given during pregnancy to boost maternal transfer of antibody to newborns and ~35 pregnant women demonstrated reasonable immunogenicity and there was increased antibody titers in newborns. Another subunit vaccine composed of a conserved region of the G protein (aa 130–230) linked to the albumin-binding domain of streptococcal protein G as a carrier (designated BBG2Na). Although protective in animals, this vaccine stimulates only low levels of neutralizing antibody. Unfortunately, when tested in a phase II clinical study some patients developed a type II hypersensitivity reaction characterized as *vasculitic purpura*. Finally, a subunit vaccine composed of purified F, G, and M

proteins has been found to be highly immunogenic in adults with induction of neutralizing antibody and to be without significant side effects. Efficacy trials in high-risk adults have not been carried out at this time.

Beginning in 1995, further attempts to attenuate a previous *ca*RSV strain by further mutagenesis yielded a series of genetically well-characterized vaccine candidates. These strains, containing nucleotide substitutions resulting in the *ca* phenotype (N, F, L genes) and *ts* phenotype (M2 and L genes), were restricted to growth in the upper respiratory tract of mice and nonhuman primates and were protected from wild-type RSV challenge. Several were tested sequentially in adults, older children, and seronegative children >6 months of age. Although two, identified as *cpts* 248/955 and 530/1009, were not sufficiently attenuated in seronegative infants, one strain (*cpts* 248/404) was evaluated in infants as young as one month. Unfortunately, it caused nasal congestion, which affected feeding and sleeping in a few of the vaccines. Although this strain also was abandoned, it was capable of inducing serum neutralizing antibody in children above age 6 months and possibly protective serum neutralizing IgA in the youngest infants.

6
Future Approaches to an RSV Vaccine

Development of a protective and safe RSV vaccine remains a formidable task. In choosing potential vaccine candidates, the target population must be considered carefully. Considering current knowledge, the ideal vaccine would at least mimic, if not improve upon, the immune response to natural infection. This includes stimulation of mucosal IgA, humoral neutralizing antibodies to both major RSV groups, and a Th_1 type cellular immune response with CTLs recognizing virus from both groups. The optimal vaccine would be immunogenic in infants less than 2 months of age and overcome the immunosuppression of maternal antibody and the generally immature immune system of the very young infant. Research to determine those viral components that contribute to virulence may also allow specific deletion of the offending region of the protein or even entire genes. In contrast, parenterally or perhaps mucosally administered subunit vaccines may be effective in previously infected children and adults to prevent reinfection, and for maternal immunization to boost transplacental delivery of antibody in pregnant women. Since natural infection only provides partial immunity, a conservative, but realistic, goal of immunization is reduction of illness severity rather than prevention of infection. In addition to safety, the successful vaccine must carefully navigate a fine line between beneficial and detrimental immune stimulation.

6.1
Nonreplicating Subunit Vaccines

Given the current state of knowledge and technical tools available, single or combined viral protein subunit vaccines, comprised of entire proteins or smaller peptides, can currently be devised and evaluated. In addition to choosing the appropriate viral antigen, route of administration (parenteral, mucosal) and inclusion of the proper adjuvant are important considerations in attempting to induce the correct immune response. Because of the

catastrophic events clouding the formalin-inactivated vaccine trials, clinical trials with inactivated subunit vaccines for infants would proceed very slowly, if at all. Adjuvants and/or immune modulators such as cytokines capable of stimulating Th_1 responses may ultimately prove useful in shifting the response to nonreplicating antigens from Th_2 to Th_1 in nature.

Another more indirect way to protect infants is vaccination of women during pregnancy, an approach being considered for a variety of infant infections. Modest increases in neutralizing antibody may be sufficient to lessen the severity of RSV infection or delay infection until the child is older and less susceptible to severe disease. The other major vaccine target group, the elderly and high-risk adults, may also benefit from immunization with a subunit vaccine.

Alternate routes of administration and newer adjuvants can significantly alter the immune response to these subunit vaccines. Intranasal administration of F or an FG chimeric protein with the mucosal adjuvant cholera toxin (CT) or its purified B subunit (CTB) induces protective mucosal and systemic immunity in mice. Although CTB is unlikely to be approved for use in humans, other mucosal adjuvants may provide similar capabilities. Mucosal immunization is also theoretically possible via the oral route, and is attractive because of its simplicity. There has been one report of an immunogenic G peptide fragment synthesized in a plant, with the ultimate goal of high yield inexpensive production with the possibility of an oral vaccine.

In addition to entire viral proteins, peptide fragments of F and G have also been proposed as potential vaccines. Regions of F, which represent neutralizing or CTL epitopes, can be synthesized. One F peptide, representing the neutralizing site from amino acids Ile221 to Glu232, elicited low level neutralizing antibody in mice but protection has not been demonstrated. In addition, a peptide representing amino acids 174–187 from the G protein provided complete protection from virus challenge, which was relatively durable. The principle advantage of a synthetic peptide vaccine is that production of large quantities is relatively simple. On the other hand, vaccination of a heterogeneous population may be difficult, if not impossible, due to the limited immune response to single epitopes.

6.2 Live Recombinant Subunit Vaccines

Replicating vectors expressing the desired RSV protein(s) may provide a viable approach to immunization. Replication incompetent vectors such as the VEE system, have the advantage of potentially inducing a Th_1 response with appropriate humoral and cellular immunity to envelope glycoproteins. Although vaccinia virus and adenovirus vectors have been developed and tested in mice and primates, they did not progress to human trials. Recently, a bovine parainfluenza type 3 virus expressing the RSV surface glycoproteins has been constructed and tested in animals. Finally, DNA vaccination is another approach to subunit immunization with a replicating antigen, although it has not been fully explored.

6.3 Live Attenuated RSV Vaccines

Despite prior frustrations, there remains interest in intranasal live attenuated vaccines. The availability of reverse genetics for production of vaccines allows virtual unlimited choices. Deletions of entire

nonessential genes is feasible and several (designated RSV ΔNS1, ΔNS2, ΔSH, ΔG) have been tested in animals and some in humans. Until the specific viral proteins or regions of proteins invoked in disease pathogenesis are identified, live vaccine development will remain relatively empiric since predictions of attenuation based upon growth *in vitro* or in experimental animals is not always precise. It may be possible that important immunogenic proteins can be left unaltered or even enhanced, yet viral growth and inflammatory responses are limited by alterations in other genes. For instance, the F and/or G proteins, which carry dominant protective epitopes, can be moved proximal to the promoter region, thus producing a virus with greater expression of F and G. Alternatively, substitutions in the intergenic sequences could enhance or diminish expression of downstream genes.

7 Conclusions

Important advances have been made in our understanding of the virology, immunology, and pathogenic mechanisms of RSV infection during the past decade. Despite rapid development in methods of vaccine preparation, advances in immune modulators and mechanisms of vaccine delivery, the prospects for an RSV vaccine remain tempered by the prior failures.

Keywords

Bacteriophage
A virus that infects bacteria and ultimately reproduces itself usually leading to the death of the bacterium.

Endonuclease
An enzyme that cleaves the internal phosphodiester bonds of a polynucleotide, in this article of a double-strand DNA.

Heterocycle
A molecule with a ring structure in which not all the atoms are carbon. The bases A, C, G, and T in DNA are aromatic heterocyles with nitrogen in place of some of the carbon atoms.

Homodimer
A protein comprising two identical polypeptide chains.

Metaphosphate
The anion PO_3^-.

Methylsulfonium Bond
A covalent bond between a divalent sulfur atom and a methyl group that has a formal positive charge on the sulfur and is thermodynamically activated for transfer of the methyl group to an acceptor molecule.

Methyltransferase
An enzyme that transfers methyl groups from S-adenosyl-L-methionine to acceptor molecules.

Motif
A sequence of amino acids that is shared (conserved) among different proteins.

Nucleophile
An atom or group with excess electrons that is capable of reacting with another atom or group that is deficient in electrons.

Palindrome
A sequence of nucleotides on one strand of a DNA duplex that is identical to the sequence in the opposite direction on its complementary strand, for example, GAATTC in one strand is the same sequence on the antiparallel, base-paired strand.

Restriction Endonuclease
An endonuclease that cleaves duplex DNA with very high sequence specificity.

Stoichiometry
The quantitative relationship between the substances in a compound or in a molecular complex.

Restriction-modification systems occur in many prokaryotes. Each consists of a restriction endonuclease that cleaves DNA after recognizing a specific sequence and a DNA methyltransferase that modifies the bacterial DNA at the recognized sequence. Methylation protects the bacterial genome from cleavage by the endonuclease. Since infecting bacteriophage DNA usually is not methylated, it is cleaved by the restriction enzyme before it can be methylated by the bacterial methyltransferase. Thus, the bacteriophage DNA is inactivated and the restriction-modification system protects the bacterial cell from bacteriophage infection. In this review, we summarize the properties of different types of restriction-modification systems and the enzymology of the enzymes involved. Our focus is primarily on the type II systems.

1 Introduction

1.1 Restriction-modification Systems

Restriction-modification (RM) systems were discovered in the 1950s by S. E. Luria and M. L. Human as well as by G. Bertani and J. J. Weigle. These groups found that after growing bacteriophages on one bacterial strain, the progeny phages could reinfect this same strain with high efficiency, but they could not infect some other bacterial strains. These observations demonstrated that the phage carries a ''label'' imparted by the strain on which it was grown. A decade later, the molecular basis of this phenomenon was elucidated by Arber and colleagues who showed that RM systems consist of two enzyme activities: a restriction endonuclease (ENase) that specifically recognizes short, often palindromic, sequences and then cleaves the DNA, and a methyltransferase (MTase) that methylates the same sequence and renders it refractory to cleavage by the ENase. The activity of the ENase is responsible for the restriction phenotype because it digests phage DNA entering a bacterial cell. In the 1970s, H. O. Smith and coworkers and H. W. Boyer and coworkers were the first to publish the purification of functional type II ENases (*Hind*II from *Haemophilus influenza* and *Eco*RI from *Escherichia coli*, respectively) and the H. O. Smith laboratory identified the first DNA recognition sequence of an ENase (*Hind*II).

The DNA of a bacterial strain carrying an RM system is protected from cleavage by the resident ENase as a result of covalent modification carried out by a DNA methyltransferase. As indicated, the MTase modifies the DNA within the recognition sequence of the partner ENase and thereby prevents endonuclease action (Fig. 1). The first RM system MTase was described in Arber's laboratory. Methylation of the DNA uses S-adenosyl-L-methionine (AdoMet) as the methyl

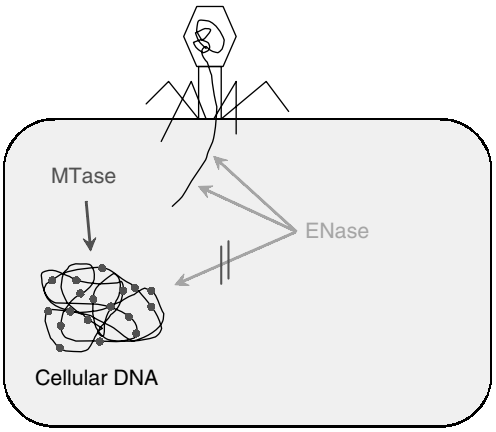

Fig. 1 Biological function of restriction/modification systems. ENases cleave unmethylated phage DNA, the bacterial genome is protected against the endonucleolytic attack by the DNA methyltransferase.

group donor and occurs at the cytosine-C5, cytosine-N4, or adenine-N6 positions of DNA depending on the particular MTase. It represents a minimal change to the molecular structure of the DNA and does not interfere with the Watson/Crick base pairing of the double helix. In all three positions of methylation, the methyl groups are positioned in the major groove of the DNA, a region where the restriction endonucleases recognize the sequence of the DNA by formation of specific contacts to the edges of the base pairs. Methylation of the recognition sequence interferes with the ENase interaction with the DNA and prevents ENase cleavage. Therefore, the activity of the ENases can be controlled by the methylation state of the DNA (see below).

Since different RM systems have different recognition sequences, the methylation pattern is, in effect, a bar code on the DNA that allows an ENase to distinguish between its own and foreign DNA. Given that DNA from bacteriophages is often not modified at the sites of the resident bacterial RM systems, RM systems efficiently protect bacteria against bacteriophage infection. However, phages grown in a bacterial cell containing an RM system will have DNA modified by the resident MTase, which explains why they can easily grow in the same strain, but not in other strains containing different RM systems that recognize different DNA sequences. RM systems control the uptake and incorporation of foreign DNA from any source into the bacterium. They are widely distributed in the bacterial and archaeal kingdoms with up to 5% of the total genome of some bacteria devoted to encoding components of RM systems. Because RM systems distinguish between self DNA and nonself DNA and protect bacteria from foreign DNA infection, they can be compared in terms of biological function to the immune system of higher eukaryotes. Like the immune system, RM systems are also involved in a molecular arms race between the invader and the host: bacteriophages have evolved many antirestriction systems such as antirestriction factors that directly inhibit the ENase or multispecific MTases that modify the phage genome at many sites and thereby provide a broad protection against the endonucleases of different RM systems.

Historically, RM systems and, in particular, ENases have been important enzymes for both the basic and applied biomolecular

sciences. The discovery of the molecular basis of RM systems was a hallmark in the molecular understanding of genetic mechanisms that was recognized with a Nobel Prize in 1978 to W. Arber, H. Smith, and D. Nathans. ENases have served as excellent model systems to study the site-directed interactions between enzymes and DNA. Many principles that later could be generalized to other systems were first recognized as a result of studies of ENases. ENases were the first tool available to manipulate DNA in a directed manner and were key players in the recombinant DNA revolution that occurred in molecular biology in the 1980s and 1990s. In addition, they enabled the first analyses of the genomes of bacteria and eukaryotes. Later, ENases made possible the first insights into the relation of DNA sequence diversity and human disease, because as a result of restriction length polymorphism studies, the cleavage patterns of DNA of different individuals could be compared and the differences correlated with pathogenic phenotypes.

2 Types of Restriction-modification Systems

2.1 Type II Systems

Three major types of RM systems, called type I, II, or III, are distinguished on the basis of their structural and functional properties. In type II systems (e.g., *Eco*RI, recognition sequence: GAATTC), the nuclease and methyltransferase activities reside in discrete enzymes, whereas they are combined in multienzyme complexes in type I and type III systems. Type II systems usually have a homodimeric ENase that recognizes a palindromic DNA recognition sequence. These homodimers carry an active center on each subunit that together catalyze DNA cleavage in both strands of the DNA. The type II methyltransferases are either monomeric or dimeric and do not interact with the restriction enzyme. The ENase and MTase bind to the DNA independently and their amino acid DNA recognition modules are different from one another. Type II systems are subdivided into many classes on the basis of functional differences, for example, whether the ENases form tetramers or whether the DNA is cut within or at some distance from the recognition site. Some type II enzymes require the interaction with two recognition sites; some will cleave both, others just one of the sites.

One of the largest subgroups of type II ENases is that of the type IIS enzymes, which interact with nonpalindromic recognition sites and cleave the DNA at a defined distance from the recognition site. The enzymes consist of two domains, one DNA recognition domain that binds to the DNA as a monomer and identifies the target sequence, and a cleavage domain, that dimerizes with a second monomer on the DNA and the dimer catalyzes the cleavage of the DNA in both strands. This dimerization of the cleavage domains is facilitated if two recognition sequences are present on the DNA. Therefore, many type IIS enzymes show an increased activity on substrates containing more than one recognition sequences. Studies with type IIS enzymes suggest that only small changes in the amino acid sequence or the acquisition or deletion of a domain can be responsible for significant changes in the specific biochemical properties of the enzyme. Consequently, many such small changes could create a continuous spectrum of ENases, many of which cannot

easily be assigned solely to one of the presently defined group subtypes.

2.2 Type I and III Systems

Type I and III systems form large supermolecular complexes containing the restriction (R) and modification (M) function. In type I systems (e.g. *Eco*B, recognition sequence: $TGAN_8TGTC$), DNA recognition for methylation and for cleavage is mediated by one S (specificity) subunit. Complexes of M_2S stoichiometry are active MTases, while M_2R_2S complexes have methyltransferase and endonuclease activities. In type III systems (e.g., *Eco*P15, recognition sequence: CTGAAG), RM complexes are active as both methyltransferase and endonuclease. The choice of reaction actually catalyzed by the multimeric enzyme depends on the methylation state of the target sequence: unmodified sites are cleaved; hemimethylated sites that are formed typically during DNA replication are methylated. Systems of both types I and III need interaction with two recognition sequences, which are asymmetric in either case. After initial binding of one enzyme complex to an unmethylated target site, the enzyme remains bound to that site and pulls the DNA using an ATP-dependent motor domain to form a characteristic looped structure. Upon collision of two enzyme molecules that are translocating along the DNA in opposite directions, cleavage is initiated. The cleavage occurs at random locations between the two target sites in the case of type I systems. Type III enzymes cleave the DNA at defined distances of up to 20 bp outside the recognition sequence. As a consequence of their different architectures, type I systems contain two motordomains and translocate along the DNA from both sides of the target sequence, whereas type III systems translocate away from one side only. Therefore, type III systems can cleave DNA only if it contains two target-site sequences in opposite orientation so that the translocating enzymes will collide. DNA cleavage by type I and III systems is stimulated or dependent on the presence of AdoMet, which is the methyl donating cofactor of the MTase subunit.

3 Mechanisms of Action of ENases and MTases

3.1 Common Features

In the following sections, we shall briefly describe some mechanistic features of the type II ENases and DNA MTases that explain how these fascinating enzymes carry out their respective biological functions. Since both classes of enzymes perform their catalytic function on DNA in a sequence-specific manner, common mechanistic elements are found in both. These include the mechanisms of DNA recognition and target-site location. The general catalytic cycle is similar in both cases (Fig. 2). The enzymes bind initially to the DNA in a nonspecific reaction, driven by electrostatic attraction between basic amino acid residues in the DNA-binding site of the enzyme and the anionic DNA. The enzymes then scan the DNA for the presence of the specific site by a process called *facilitated diffusion* in which they stay in close spatial contact with the DNA. After having identified a specific site, the formation of several base-specific contacts usually triggers characteristic conformational changes of the enzyme and the DNA. This mutually induced fit activates

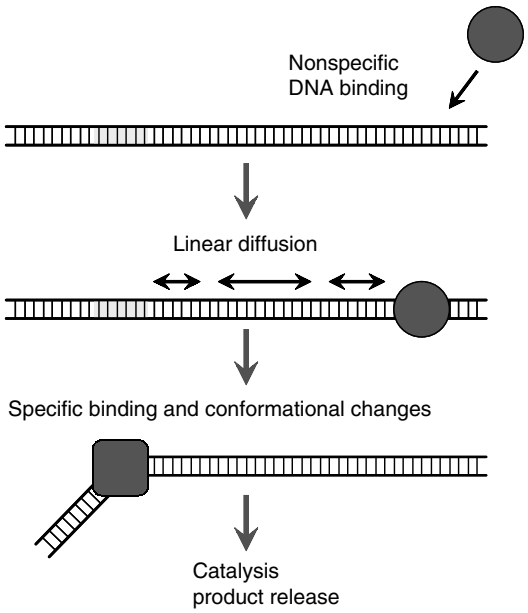

Fig. 2 Catalytic cycle of restriction endonucleases and DNA methyltransferases. The yellow box indicates the target site (see color plate p. xxxi).

the catalytic center leading to the sequence-specific DNA cleavage or the methylation reaction. After DNA cleavage or methylation, release of the modified DNA is often the rate-limiting step of the reaction under multiple-turnover conditions.

4
Catalytic Mechanism of ENases

4.1
Structures of ENases

Most structural information is available for homodimeric type II ENases (see Fig. 3 for an example). The comparison of the structures of protein–DNA complexes of several ENases revealed significant differences in their three-dimensional structures. However, most contain some conserved structural elements in the core of the enzymes that are characterized by a mixed five-stranded ß-sheet flanked by α-helices. The active site amino acid residues are located on this structural core at equivalent positions in many structures. The active site of many restriction enzymes is characterized by a weakly conserved PD. . .(D/E)XK amino acid sequence motif. The PD part of the active site is located in a turn; the remaining residues lie on the edge of a ß-strand. The three-dimensional structure of the conserved element brings together the two conserved acidic residues of the motif such that they can form the binding site for the catalytic magnesium ion that is an essential cofactor for these enzymes. The lysine in the active site motif contributes to the catalytic mechanism as well (see below). Interestingly, other nucleases including λ-exonuclease, MutH and Vsr have a similar fold constituting their active site.

Most of the type II ENases encircle, to a greater or lesser extent, the DNA in their specific DNA complex, allowing them to form an extensive set of interactions both to the major and minor grove of the DNA

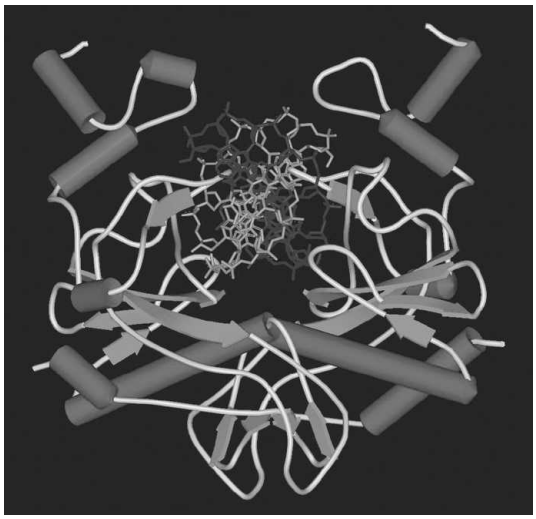

Fig. 3 Crystal structure of the *Eco*RV restriction enzyme in complex with specific DNA. The homodimeric protein is shown in a schematic view, colored according to the secondary structure, with α-helices in red, β-sheets in blue, and loops in gray. The DNA strands, which are viewed perpendicular to the helix axis, are colored blue and orange (see color plate p. xxxii).

as well as to the phosphodiester backbone (Fig. 3). On the basis of the orientation and structure of the conserved secondary structure elements, ENases can be subdivided into two large groups, represented by the first two enzymes whose structures were solved: *Eco*RI and *Eco*RV. With structures becoming available for more and more ENases, some turn out to be closely related, for example, the *Eco*RI and *Mun*I enzymes that recognize GAATTC and CAATTG, respectively.

4.2 Mechanism of Target-site Location

Since restriction endonucleases and DNA methyltransferases are present at the same time in the cell, they compete kinetically for their target site. Destruction of the incoming bacteriophage DNA dictates that the restriction enzyme finds its target site faster than the methyltransferase. Localization of specific recognition sites in the sea of nonspecific sites is a challenging process for an ENase (A six-base-pair-recognizing enzyme, for example, has just one target site every $4^6 = 4096$ sites in a DNA of 50% A + T composition.). Target sites can be discriminated from nontarget sites only during formation of the sequence-specific contacts between enzyme and DNA. However, this is not possible during the initial phase of complex formation that is mainly driven by ionic interactions. Consequently, most binding events between ENases and DNA will result in binding to a nontarget site, that is, to nonspecific DNA.

After the initial binding event, the enzyme searches for its target site by a one-dimensional movement on the DNA, which accelerates target site location by two mechanisms. First, it reduces the search space from three dimensions to one, and second, it abrogates the necessity for the enzyme to dissociate from the DNA after each binding event, which is particularly important, because DNA release is a slow step in protein–DNA interactions. Restriction enzymes were among the earliest examples in which facilitated diffusion was shown to be effective in target-site location. During facilitated diffusion, the

enzymes accurately scan the DNA sequence. The actual mechanism of this process includes a sliding movement of the enzyme on the DNA and a ''hopping'' process composed of repeated micro dissociation/reassociation reactions. The contribution of both processes varies from enzyme to enzyme and depends on the average distance traveled on the DNA. Scanning of short distances is most efficiently performed by a sliding movement, whereas at longer distances hopping becomes effective.

In addition, tetrameric enzymes can make use of intersegmental transfer, a process during which two binding sites on the protein interact simultaneously with two different parts of the DNA. One binding site can release the DNA and the other remains bound to another site without causing complete dissociation of the enzyme from the DNA. Thereby, the enzyme can make efficient long-range ''jumps'' on the DNA, which in combination with short-range scanning in the vicinity of each site, produces an efficient target-site searching strategy. This mechanism may explain why some ENases function as tetramers.

4.3 Mechanism of DNA Recognition

DNA recognition by ENases has been investigated by examination of the structures of ENases in complexes with their specific DNA. In most cases, the base pairs of the target site are contacted by several specific interactions, including hydrogen bonds to the edges of the bases in the major and minor grove (Fig. 4) and hydrophobic interactions to the bases and the methyl group in thymidine. In addition, the phosphodiester backbone is contacted by numerous hydrogen and ionic bonds. Both kinds of ionic bonds to the bases and to the backbone are sometimes mediated by interstitial water molecules that bridge the amino acid residue and the DNA. In many, but not all, cases, specific complex formation is accompanied by more-or-less dramatic changes of the DNA structure, which may involve bending, unstacking, or unwinding. Thereby, in a mutually induced fitting of enzyme to DNA, a tight complex of complementary surfaces is formed. Specific DNA binding is accompanied by the release of bound water molecules and counterions

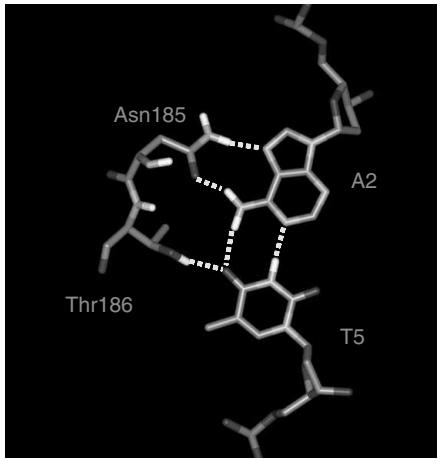

Fig. 4 Example of the specific contacts of the *Eco*RV restriction enzyme to its DNA. Asn185 and Thr186 contact the A2 and T5 base pair in the G<u>A</u>TATC/GATA<u>T</u>C recognition sequence by specific hydrogen contacts.

from the ENase and the DNA. The methylation of the target base by the partner MTase interferes sterically with this close approximation of the ENase and the DNA, explaining the energetic basis for the lack of activity of ENases at methylated target sites.

The numerous interactions (direct contacts to bases and to backbone and water-mediated contacts to both) in the network of bonding that occurs between ENases and specific DNA guarantee that each base pair is contacted by several specific noncovalent bonds and provides the structural basis of the exquisite sequence specificity of ENases that ensures they do not kill their host cells through nonspecific cleavage. Typically, these enzymes cleave any sequence differing by one base pair from the canonical site at rates that are orders of magnitude reduced; sites differing at more than one base pair are refractory to cleavage. The mechanistic basis for this extreme sequence specificity is that the scissile phosphodiester bond enters the active site only after the conformational change of DNA and enzyme that occurs in the specific complex. Therefore, DNA cleavage can occur only after binding of the enzyme to a specific site on the DNA.

The evolutionary history of this high degree of sequence specificity of ENases can be understood, because cellular DNA is protected against cleavage by the MTase only at the specific sites. Therefore, nonspecific double-strand cleavage of the bacterial DNA by ENases is toxic and has been strongly counterselected during evolution. In addition, ENases usually introduce only a single-strand break at nontarget sites, which can be easily repaired by DNA ligase, in contrast to their double-strand cut at target sites. Because of their very high degree of specificity, ENases have been refractory to all attempts to change their specificity by protein design. In particular, unsuccessful trials to design new contacts between ENases and DNA by site-directed mutagenesis have demonstrated that enzyme variants that carry amino acid exchanges at critical positions usually are catalytically inactive. This property ensures that erroneous proteins that are formed in the cell after rare misincorporations of amino acid residues during protein biosynthesis will not act as nonspecific nucleases or ENases with altered recognition specificity and kill the cell.

It is interesting to note that the sequence-specific contacts are formed by different segments of the protein in the various structural families of ENases. For example, in *Eco*RI a structure similar to a ß-strand is located in the major groove of the DNA and in *Eco*RV two loops of protein mediate sequence recognition. On the other hand, families of enzymes exist that use similar structural approaches to recognize related sites, for example, the *Eco*RI/*Mun*I pair or in the large subfamily of ENases containing *Ngo*MIV (GCCGGC) that have a GG dinucleotide in their target sequence and use a conserved RXXR motif for its recognition. In contrast, the interaction of *Bam*HI (GGATCC) and *Bgl*II (AGATCT) with DNA is different, although both enzymes recognize the same GATC central tetranucleotide.

4.4 Mechanism of DNA Cleavage

Despite being studied for decades, the detailed catalytic mechanism of ENases remains incompletely resolved. One obvious source of uncertainty is that different crystal structures revealed one, two, or

three divalent cations bound at or near their active sites. These observations led to models requiring one or two metal ions for catalytic function. Furthermore, the relationships of the metal ions observed in various structures to the activity of the enzymes in solution is not clear, since most crystallizations were carried out at much higher concentrations of the divalent metal ions than is commonly used for cleavage in solution.

DNA cleavage by ENases always produces a 5′ phosphate and a 3′ OH. It is initiated by the in-line attack of a water molecule on the scissile phosphodiester group (Fig. 5). Chemically, this nucleophilic attack is difficult, since the phosphodiester group carries negative charge and efficient neutralization of this charge is an important catalytic requirement. All ENases appear to recruit a Mg^{2+} ion for that purpose along with basic residues that contribute to charge neutralization – most frequently the lysine often found in the PD. . .(D/E)XK catalytic motif whose aspartic or glutamic acid residues function in positioning of the metal cation. The second important function of the enzyme is to accelerate the hydrolytic reaction by stabilization of the leaving 3′-O^- alcoholate group by protonation. In most models, this role is attributed to a water molecule bound in the ligand sphere of the Mg^{2+} ion, which explains the absolute requirement for this metal ion that in most cases can be replaced by Mn^{2+}, sometimes also by Co^{2+}, but usually not by other ions.

Whereas this consensus view on the mechanism is widely accepted, other details are unclear. For example, an S_N2-like in-line attack would also require activation of the attacking water. This function has been attributed to another metal ion, the neighboring phosphodiester group, lysine, arginine, or aspartic acid residues in the different mechanistic models. However, for the hydrolysis of a phosphodiester bond, a more S_N1-like dissociative mechanism could also hold in which the bond to the leaving group is almost completely broken before the attacking nucleophile comes in. In this mechanism, a highly reactive metaphosphate intermediate that readily reacts with water is formed. Therefore, activation of the attacking water might not be necessary, if a dissociative mechanism functions. In this model, the proton leaving the attacking water during the reaction is transferred to bulk solvent. To yield the stereochemistry observed upon ENase cleavage, the metaphosphate that would be produced during a dissociative mechanism would

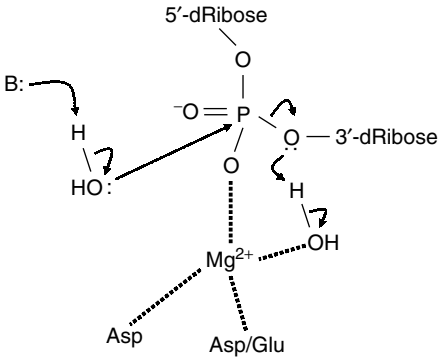

Fig. 5 Model of the catalytic mechanism of restriction endonucleases. The catalytic metal ion is bound by two acidic amino acid residues located in the PD. . .D/EXK motif. The nature of the base responsible for the deprotonation of the attacking nucleophile is not known and may vary between different ENases.

have to be positioned by the enzyme in a stereochemically defined manner such that an inversion of configuration always occurred.

5
Catalytic Mechanism of DNA MTases

5.1
Mechanism of DNA Methylation

All DNA MTases use the coenzyme S-adenosyl-L-methionine (AdoMet) as the donor of an activated methyl group whose activated methylsulfonium bond can be easily attacked by a nucleophile to achieve the methylation. However, direct methylation of either the exocyclic amino groups of adenine and cytosine or of the C5-position of cytosine is a difficult chemical task because the N1 and N3 positions of adenine and cytosine, respectively, are the favored sites of nucleophilic attack and the C5 of cytosine is intrinsically resistant to nucleophilic attack. For adenine and cytosine in duplex DNA, only the N3 position of adenine is readily alkylated by nucleophilic reagents. To overcome these intrinsic lacks of reactivity, the two families of DNA MTases, N-Mtases, and C-MTases, have evolved highly sophisticated reaction mechanisms. Both mechanisms have in common the need for close contact between the enzyme active site and the target base. Such proximity is not possible with the target base buried within the DNA double helix. In a seminal structural study, X. Cheng, R. Roberts, S. Klimasauskas, and coworkers demonstrated that the cytosine-C5 MTase HhaI completely flips its target base out of the DNA double helix during catalysis – an unprecedented, dramatic conformational change in the DNA that solves the accessibility problem (Fig. 6).

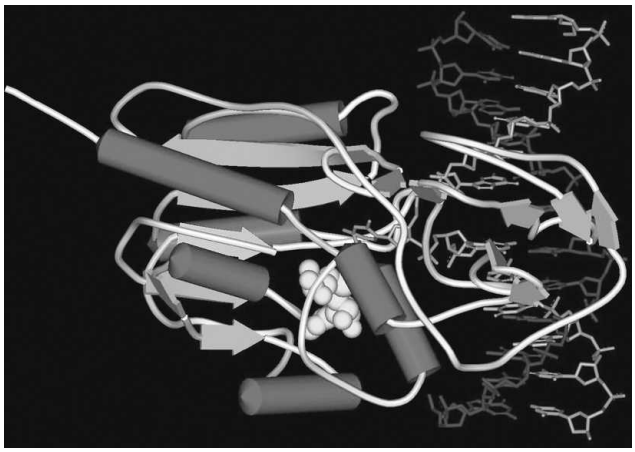

Fig. 6 Structure of the HhaI DNA-(cytosine-C5)-MTase in complex with specific DNA. The flipped target cytosine is readily visible in this view of the enzyme. The protein is shown in a schematic view, colored according to the secondary structure, the DNA strands are colored blue and orange and the AdoMet coenzyme is shown in yellow (see color plate p. xxxii).

5.2 Reaction Mechanism of C5-MTases

Methylation of the C5-position of cytosine follows a two-step reaction mechanism first proposed by Daniel Santi (Fig. 7). In the first step, a cysteine residue in the active site of the DNA MTase performs a nucleophilic attack on the C6-position of the cytosine that is flipped out of the DNA and bound in a hydrophobic pocket of the enzyme. Thereby, a transient carbanion is generated, which is stabilized by a conserved glutamic acid residue that hydrogen bonds to the flipped base and protonates the N3 atom of the base. Since the carbanion has a high negative charge density at position 5, the activated base can attack the methyl group of the cofactor yielding a stable intermediate comprising a covalently linked complex of the methylated cytosine and the MTase. The catalytic cysteine and glutamic acid residues are located in two highly conserved amino acid motifs found in Cytosine-C5 MTases, the PCQ motif and the ENV motif also called *motif IV* and *motif VI*, respectively. The second step of the reaction resolves the covalent intermediate. It is

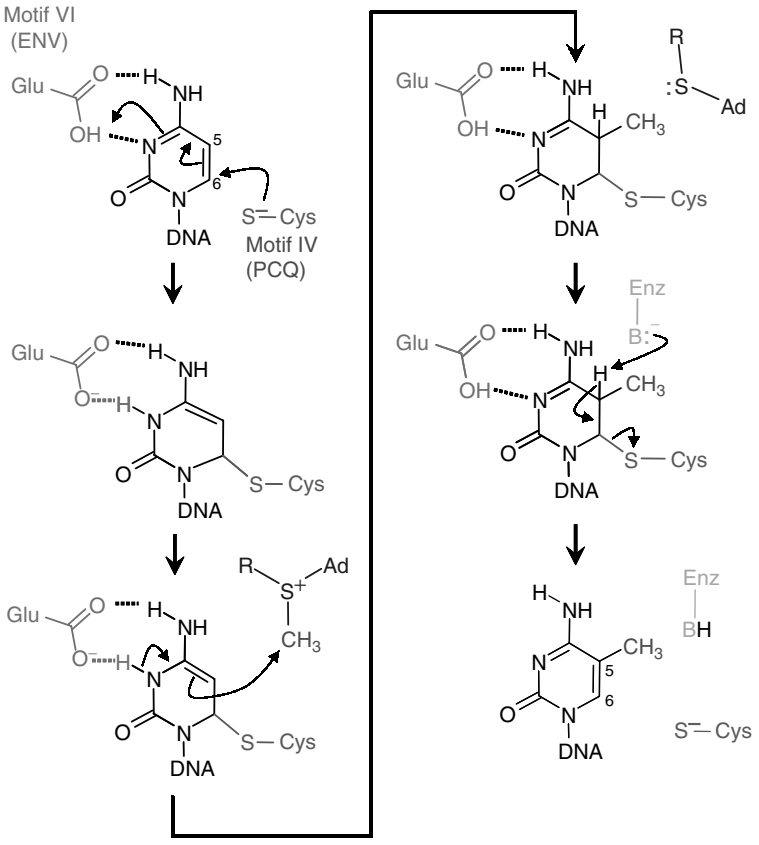

Fig. 7 Catalytic mechanism of DNA-(cytosine-C5)-MTases. (See color plate p. xxxv).

initiated by deprotonation of C5 catalyzed by an unknown proton acceptor, leading to the elimination of the cysteine residues and re-establishment of aromaticity.

The mechanism is supported by several lines of evidence. The covalent complex has been detected in crystal structures and in biochemical studies, the catalytic cysteine and glutamic acid residues are highly conserved in all cytosine-C5 Mtases, and mutational analyses have supported their involvement in catalysis. In addition to these elements of covalent and acid-base catalysis, MTases facilitate the methylation reaction by proper positioning of the substrate and the cofactor in the active site and by tight binding to the transition state of the reaction.

5.3 Mechanism of N-MTases

Methylation of either adenine and cytosine residues at their exocyclic amino group, in contrast to their N1 or N3 positions, respectively, presents a difficult chemical problem because in each case the substrate amino group is part of an electron poor, heterocyclic aromatic system. The free electron pair formally present at the exocyclic amino groups is delocalized into the aromatic system and is not as readily available for nucleophilic attack on the AdoMet as are the heterocyclic ring nitrogens. The catalytic center of the adenine-N6 and cytosine-N4 MTases (N-MTase) is characterized by a (D/N/S)PP(Y/F) motif. Involvement of this amino acid sequence element in catalysis was demonstrated in several site-directed mutagenesis studies carried out with N-MTases. The reaction mechanism of the N-MTases is illustrated by the structure of the TaqI adenine-N6 MTase. The side chain of the active site asparagine and the backbone carbonyl group of the proline residue next to the asparagine of the active site tetrapeptide (NPPY in M.TaqI) contact the exocyclic amino group of the flipped adenine target (Fig. 8). Since the hydrogen-bond acceptors are presented in a tetrahedral geometry, the hybridization

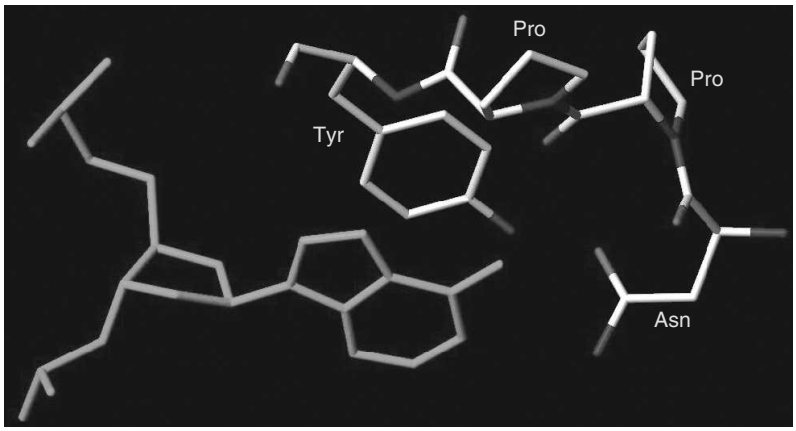

Fig. 8 Crystal structure of the *Taq*I adenine-N6 MTase. The flipped base (shown in green) is stacked on the tyrosine residue of the conserved (D/N/S)PP(Y/F) motif. The exocyclic amino group is contacted by two hydrogen-bond donors (the Asn and Pro residue in the active site motif) (see color plate p. xxviii).

of the amino group changes from sp^2 to sp^3, which leads to the localization of the free electron pair at the nitrogen atom. The flipped base is stabilized by a π-stacking interaction to the aromatic amino acid residue in the (NPPY) motif. Proper positioning of the DNA-flipped base and the AdoMet is critical for catalysis in N-MTases as it is in C5-MTases.

Consistent with the similarity of their active site motifs and the chemistry of the methylation reaction, the amino MTases do not show absolute specificity for the flipped base that they methylate. A cytosine positioned in the DNA recognition sequence of some adenine-N6-MTases can be methylated at the N4 position. Analogously, an appropriately placed adenine can sometimes be methylated at the N6 position by a cytosine-N4-MTase. These reactions occur with reduced efficiencies, but they indicate that the catalytic mechanisms of adenine-N6 and cytosine-N4 MTases are similar. In addition, the HemK enzymes, found across the phylogenetic tree of N-MTases, contain this motif and methylate glutamine at the N5 position, which also contains an amino group conjugated to an electron poor π-system. These findings suggest that the (D/N/S)PP(Y/F) sequence is a versatile motif for the methylation of different target molecules. One can envisage that other enzymes containing this motif might have even more, as yet undescribed, substrates, for example, arginine.

5.4 Structures of MTases

All DNA MTases comprise two domains, one large and one small. The large domain consists of a central mixed ß-sheet, flanked by α-helices. It is folded into two subdomains, each of which forms a hydrophobic pocket. One of these pockets is used as the coenzyme-binding site and the other as the binding site for the flipped target base. The AdoMet binding site is characterized by conserved amino acid motifs that are found in most AdoMet-interacting enzymes, with conserved motif I [(D/E/S)XFXGXG] contributing important contacts to the AdoMet. Cytosine-C5-MTases and N-MTases show a striking similarity in the structure of their catalytic domains, with important catalytic residues [motif IV: PCQ in the case of cytosine-C5 MTases and (D/N/S)PP(Y/F) in the case of N-MTases] occupying equivalent positions in the 3D-structures of both MTase families. The second, smaller domain of DNA MTases is more heterogeneous in size and structure. It contains most of the residues that mediate sequence-specific recognition of the DNA. Therefore, the variability of the target sequence is reflected by the loss of sequence conservation of the small DNA MTase domains.

5.5 Mechanism of DNA Recognition

DNA recognition by MTases, as with ENases, arises from sequence-specific contacts of the enzymes in the major and minor grooves of the DNA as well as to its phosphodiester backbone. The small domain of the MTases contacts the DNA from the major groove side, and the body of the large domain interacts with the minor groove. In addition, loops of the catalytic domain contribute to sequence recognition in some enzymes. Depending on the particular enzyme, specific complex formation sometimes, but not always, leads to strong bending of the DNA. Unfortunately, structural information is available presently only for enzymes that do not induce bending of the DNA.

Although only a few have been studied, the sequence specificity of different DNA MTases appears to vary dramatically. Some MTases display a high specificity that may be comparable to that of restriction enzymes, whereas others interact with the DNA in a much more relaxed manner such that sites differing from the consensus target site are modified at reasonable rates. It should be noted that inaccurate MTases are much less toxic to the cell than are inaccurate ENases. Therefore, the major evolutionary pressure on MTases is to maintain an effective modification of the bacterial DNA at the ENase recognition site. Occasional methylation of nontarget sites usually does not have major, immediate effects. As a consequence, RM systems are steadily evolving and are regularly changing or modifying their recognition sites by broadening the specificity of their MTases and occasionally acquiring by horizontal gene transfer a new ENase whose specificity matches the broadened specificity of the MTase. Most likely, MTases with relaxed specificity have been caught in the act of molecular evolution and have not yet optimized selectivity for their new target site.

5.6 Mechanism of Target-site Location and Lack of Processivity of Methylation

Like the restriction enzymes, the DNA MTases of RM systems use facilitated diffusion to accelerate the search for target sites. In this mechanism, the enzyme first binds to the DNA at a nonspecific site in a very fast reaction that often is close to the theoretical limit for a bimolecular association process between macromolecules. Then, the enzyme follows the DNA in a one-dimensional random movement.

One interesting aspect in the target-acquisition mechanism of the DNA MTases is the way in which several target sites may be modified when they reside on the same DNA molecule. Enzymes can react with substrates containing several target sites in two principal ways – processively or distributively. In a processive reaction, after one turnover, the enzyme remains bound to, or closely associated with, the same substrate molecule, moves to the next target site, and modifies it a second time, and so on. Therefore, in a completely processive reaction, a given DNA molecule is modified at all its target sites before the enzyme dissociates completely from the DNA. In contrast, in a distributive reaction the enzyme releases the DNA after each turnover and then rebinds to the same DNA or to a different DNA molecule. As a consequence of these two different mechanisms, the distribution of substrates, methylation intermediates, and products in a reaction mixture are completely different: methylation intermediates are not observed in a processive multiple-turnover reaction, whereas intermediates are necessarily formed in a distributive reaction. Recently, experiments with different MTases, demonstrate that the solitary M.SssI, the CcrM MTase, *E. coli* dam, and the mammalian Dnmt1 enzymes methylate DNA in a highly processive reaction. In contrast, the RM enzymes M.*Hha*I, M.*Hpa*I, *Eco*RI, and *Eco*RV react distributively. This difference is particularly striking in the case of the *Eco*RV-*E. coli* dam pair, because these enzymes share high sequence similarity and show overlapping target-site specificity, GATATC and GATC, respectively, where the common sequence is underlined.

The processive and distributive mechanism reflects the biological roles played by the respective enzymes. RM systems

protect cells from bacteriophage infections by endonuclease cleavage of the invading phage DNA. The RM MTase prevents cleavage of the host genome by methylation. However, if the MTase modified the incoming DNA too rapidly, the phage DNA would be protected and lethal. The distributive reaction mechanism of the RM MTases helps prevent complete methylation of any one molecule thereby leaving it vulnerable to the restriction enzyme, since cleavage of one site only is usually sufficient for phage inactivation. In agreement with this model, all RM MTases examined show a distributive reaction. Mechanisms such as compartmentalization or tight control of the expression levels of both types of enzymes could also ensure proper RM MTase function. Because rapid methylation of the chromosomal DNA after replication is desirable, the solitary MTases would not be selected against by evolution.

The difference in the order of DNA and AdoMet binding provides an explanation for the difference in processivity between *Eco*RV and *E. coli* dam. *Eco*RV first binds to the cofactor and then to the DNA, whereas *E. coli* dam prefers the opposite binding order. Microscopic reversibility dictates that the order of DNA and cofactor release must reflect their order of binding. *Eco*RV will release the DNA first and the cofactor second. The obligate release of DNA first precludes *Eco*RV from modifying DNA in a processive fashion, because the enzyme cannot exchange the product AdoHcy with AdoMet while bound to the DNA. The exchange of the cofactor in the ternary complex of M.*Eco*RV may be prevented by slight conformational changes that could block a channel needed for cofactor exchange. This effect of bound DNA on the cofactor-exchange order illustrates how seemingly subtle effects on the structure and mechanism of an enzyme can have profound effects on the function, for example, in this case, ensuring a distributive reaction rather than a processive one.

Keywords

Apoptosis
The process of programmed cell death.

E2F
A transcription factor that regulates S-phase genes.

LOH
Loss of heterozygosity.

Proband
The very first individual in a family to be diagnosed.

RB1
Retinoblastoma tumor susceptibility gene.

Retinoblast
A precursor cell that becomes a retinal cell.

SV40
Simian virus 40 DNA tumor virus.

TAg
Simian virus 40 large T antigen oncoprotein.

Tumor Suppressor
A gene that prevents a cell from becoming a tumor.

Retinoblastoma is a rare malignant tumor initiated by the inactivation of both alleles of the retinoblastoma tumor susceptibility gene, *RB1*, in a developing human retinal cell. Surprisingly, the protein (pRB) encoded by *RB1* is an important transcription factor. Cell cycle control by pRB is mainly accomplished by transcriptional repression of genes required for cell cycle progression. Control of differentiation by pRB is achieved by the activation of transcription. Almost every kind of tumor has disruption in the retinoblastoma pathway associated with tumor progression, but germline mutation of the *RB1* gene predisposes children to a 95% specific risk of developing retinoblastoma and a significant but much less risk of second primary tumors, such as osteosarcoma and melanoma. Ongoing intense efforts to define the features of the retinal cell that is sensitive to *RB1* loss have potential to once again broadly influence the understanding of cancer in general.

1 Retinoblastoma, Cancer of Infants

Retinoblastoma most commonly is diagnosed only when tumor fills one or both eyes, and the parents notice a white gleam from the pupil of the baby's eye. Often, the diagnosis is definitive based on clinical examination and CT Scan that reveals calcification within the tumor. When only one eye is affected, the preferred treatment is almost always removal of the eye, which is usually curative. When both eyes are involved, the choice of treatment for each eye depends on the size and extent of tumor, the risk of tumor spreading outside the eye, and the risk to vision of the treatment. The new International Intraocular Retinoblastoma Classification (IIRC), which stages each eye with retinoblastoma and predicts the likelihood of treatment curing the eye, is being validated through a global Internet survey.

Eyes with advanced tumor at risk to spread outside the eye, and virtually no possibility of useful vision even if the tumor is controlled (IIRC Group E), are removed. Eyes with medium or large tumors (IIRC Groups B, C, D), no risk of extraocular tumor and some possibility of vision, are now commonly treated by systemic chemotherapy combined with laser and cryotherapy to destroy physically any surviving or chemotherapy-resistant tumor cell. Eyes with small tumors not immediately adjacent to the center of vision or the optic nerve (IIRC Group A) are treated with laser and cryotherapy. Cure is usually obtained within 2 to 4 years. Late recurrences are rare. The fraction of children who lose both eyes to retinoblastoma is now small. Most children end up with vision in atleast one eye.

Retinoblastoma tumor cells may escape from the eye and spread through the optic nerve to the brain or through the blood to grow preferentially in the bone marrow. Until recently, metastatic retinoblastoma was incurable. There are now several reports of long remissions and, possibly, cure following intensive systemic chemotherapy, chemotherapy given into the meningeal space, and megadoses of chemotherapy to destroy any surviving tumor cells followed by stem cell transplant to reconstitute the bone marrow.

Radiation therapy is very effective in controlling retinoblastoma tumor growth.

However, radiation of children with *RB1* mutant alleles greatly increases the risk of a second primary cancer later in life, from the already high risk that the mutant *RB1* allele imposes. Chemotherapy also carries a risk of induction of leukemia, but the magnitude of this risk has not been established.

2 Genetic Principles of Cancer Discovered through Retinoblastoma

The tendency for retinoblastoma to be transmitted in families as an autosomal dominant trait was recognized in the early 1900s. The location of the predisposing gene on chromosome 13q was suggested by the observation in the early 1960s that large deletions involving chromosome 13q14 were associated with retinoblastoma and other abnormalities. However, bilateral retinoblastoma was thought to be a unique special case of cancer in which genetics played some role, while nongenetic mechanisms were presumed, erroneously, to underlie common forms of cancer.

In 1971, Alfred Knudson proposed, from simple analysis of age of diagnosis of bilateral versus unilateral retinoblastoma, that both hereditary (usually bilateral) and nonhereditary (always unilateral) retinoblastoma are initiated by two mutational events, M1 and M2. In 1973, Comings proposed the possibility that these two events could be the two alleles of one gene whose normal function would be suppression of tumors.

2.1 Genetic Locus of the Retinoblastoma Gene

Proof that retinoblastoma tumors had mutation of both alleles of the 13q14 predisposing gene was obtained when genetic markers could distinguish the two alleles. Although the *RB1* gene was not yet cloned, markers near the RB chromosomal locus showed that the heterozygous 13q14 allele associated with the presence of retinoblastoma in members of a family was often the only retained allele in retinoblastoma tumors (loss of heterozygosity, LOH). LOH for 13q14 was observed in both hereditary and unilateral, likely not hereditary, retinoblastoma tumors, proving that Coming's predictions are correct. Both hereditary and nonhereditary retinoblastomas are initiated by mutation of the same tumor suppressor gene. The retinoblastoma studies opened the way to find other tumor suppressor genes in which mutation initiates a wide variety of other cancers. Through the 1980s, numerous papers reported the chromosomal localization of disease-specific tumor suppressor genes by searching for LOH in tumors. Cancer was clearly demonstrated to be the most common somatic genetic disease.

In sporadic bilateral retinoblastoma patients, the M1 occurs either *de novo* in a parent and is transmitted via the germ cells or during embryonal development. Retinoblastoma is initiated when the remaining normal allele is inactivated (M2) in a retinoblast cell carrying M1. Sporadic unilateral retinoblastoma occurs in children with normal *RB1* germline alleles, who develop rare somatic mutations of both alleles (M1/M2) in a developing retinal cell.

Bilaterally affected patients all have one germline *RB1* mutant allele, which results in autosomal dominant transmission of the predisposition to retinoblastoma. Unilaterally affected patients have only a 15% chance that they carry a germline *RB1* mutant allele. Therefore, the standard

approach for unilateral patients is to test the retinoblastoma tumor DNA to identify the two mutant *RB1* alleles and then test the blood DNA for each mutant allele. In this way, a negative result generally rules out heritable retinoblastoma in the unilateral proband, although mosaicism is never excluded. Antecedent relatives are excluded from risk, and future offspring of the unilateral patient can be tested for the mutant alleles found in the tumor of their parent, just in case the parent had undetected germline mosaicism.

The majority of children with heritable retinoblastoma have newly acquired *RB1* mutations. Most frequently, it is the paternal *RB1* allele that is mutated, presumably because of the increased risk of mutation of sperm relative to ova. About 10% of new *RB1* germline mutations can be shown to be mosaic, present in less than 50% of the *RB1* DNA and in only a fraction of the cells of the proband. Clinically, mosaicism may become obvious when a parent has more than one child with retinoblastoma but does not show in blood the mutant *RB1* allele present in the children. Mosaicism cannot be inherited since the predisposing mutation must occur during the development of the embryo.

2.2 Retinoma

Nonprogressing retinal lesions were originally considered to represent ''spontaneous regression'' of retinoblastoma. Retinoma is a preferable name, which does not imply knowledge of a mechanism. A retinoma is typically a translucent-gray retinal mass, frequently associated with calcification and hyperplasia of the retinal pigment epithelium, unlike the actively proliferating retinoblastoma that shows calcification but appears opaque-white. Pathology of retinoma (also called *retinocytoma*) shows a varied arrangement of neuronal cells with photoreceptor differentiation, axons, Müller glia cells, and astrocytes.

Although retinomas are ''benign,'' they can undergo malignant progression to retinoblastoma. Particularly in a young child, such tumors must be watched regularly for indication of transition to retinoblastoma. *RB1* germline mutations predispose to both retinoma and retinoblastoma in the same patient and in other members of a family who have the mutant *RB1* allele. Although no molecular analysis of retinoma has been reported, germline *RB1* mutations have been identified in several patients with bilateral or unilateral multifocal retinomas as their only clinical manifestation.

3 Spectrum of *RB1* Mutant Alleles and Risk Prediction

RB1 mutations are spread throughout the gene including the promoter, most exons, and splicing regions of introns (Fig. 1). More than 50% of *RB1* mutations have been found only once, and the majority of germline mutations originate in the proband. Molecular identification of *RB1* mutations supports accurate determination of the risk of retinoblastoma in relatives.

RB1 mutations are most frequently ''null'' mutations that are out of frame and result in premature STOP codons (Fig. 1). Premature truncation of translation in turn triggers nonsense-mediated decay, unstable mutant mRNA, and no detectable pRB. The only significant hot spots for *RB1* mutations are the ''recurrent'' mutations,

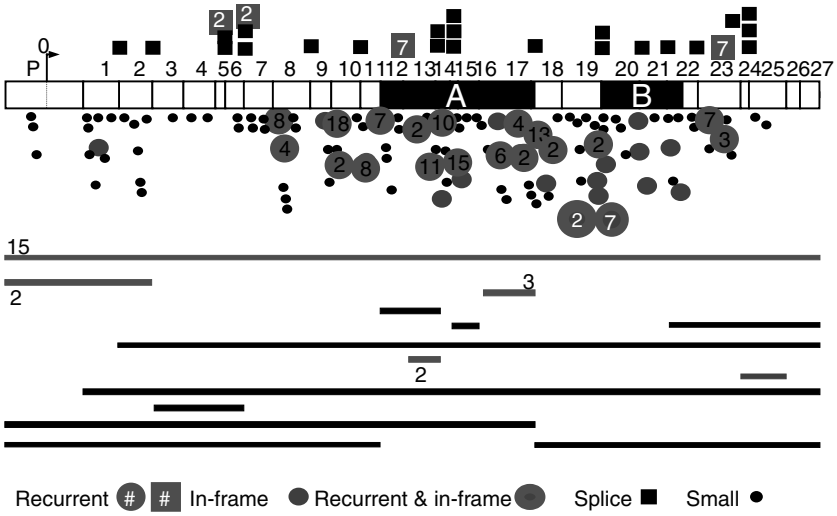

Fig. 1 Retinoblastoma-initiating mutations are distributed throughout the *RB1* gene. Of the 230 germline mutations, 53% have been reported only once. Recurrent mutations are shown in red, with the number of occurrences indicated in the box. In-frame mutations are shown in blue. Boxes indicate splice mutations. Circles indicate small point or few nucleotide mutations. Lines indicate lengths of deletions. (See color plate p. xxxiii).

most commonly CGA (arginine) mutating to TGA (STOP) because CpG codons are prone to mutate to TG. Missense mutations almost invariably involve the A/B "pocket" domain of pRB, which is critical in many protein interactions of pRB.

In bilateral probands, 93% of the germline mutations are null, 6% are in-frame, and 1% are promoter. In the uncommon unilateral germline probands (both familial and sporadic), the ratios of null (57%), in-frame (40%), and promoter (3%) mutations are very different. The presence of unilateral tumor indicates reduced expressivity of the germline *RB1* mutation, manifesting as fewer than expected tumors, reducing the likelihood of a null allele. Reduced penetrance/expressivity *RB1* mutant alleles retain enough activity to prevent some, but not all, retinoblastoma tumors. The types of mutant alleles identified in retinoblastoma tumors, presumably of somatic origin (88% null, 3% in-frame, and 8% promoter methylation), are different again.

The second *RB1* allele (M2) is lost by LOH in 52% of sporadic retinoblastoma tumors. The likelihood that the M2 event is LOH also varies with the type of M1 event. While 50% of the tumors with M1 whole gene and exonic deletions show LOH, 88% of tumors with methylation of the promoter show LOH. The biological reasons for these differences are unknown.

4 The Retinoblastoma Gene and Protein

The *RB1* gene was cloned by identification of a chromosome 13 DNA clone that was totally deleted from a retinoblastoma tumor. This was correctly interpreted to be LOH for a deleted allele, and the clone

turned out to be located within an exon of the *RB1* gene. The 190-kb *RB1* gene transcribes a 4.7-kb RNA in 27 exons. Comparison of the human and mouse *RB1* genes shows 80% homology in the first 235-bp upstream of the initiating methionine, 89% homology in the coding sequence, and 77% homology in the 3′ untranslated region. The human and mouse promoters contain binding sites for the transcriptional elements ATF, SP1, and E2F, but are devoid of TATA and CAAT boxes. The human and mouse proteins show 91% identity, suggesting that the function of this protein is highly conserved. The retinoblastoma protein (pRB) is a nuclear phosphoprotein of 928 amino acids that runs as a doublet of molecular weight 110–114 kDa on SDS polyacrylamide gel electrophoresis. The slower migrating band corresponds to the phosphorylated species of pRB.

RB1 function is abrogated either by deletion or mutation in retinoblastoma. In most other tumors, *RB1* is mutated or functionally inactivated, confirming that *RB1* is a tumor suppressor gene. The reintroduction of *RB1* into certain cells that have nonfunctional *RB1* alleles can suppress proliferation. For example, retroviral introduction of *RB1* into the retinoblastoma cell line WERI-Rb27, the osteosarcoma cell line Saos2, the prostate carcinoma cell line DU145, and the bladder carcinoma cell line HTB9 resulted in morphological changes, reduction in growth rate, reduced colony formation in soft agar, and reduced tumorigenicity in nude mice. However, introduction of pRB into the U2OS osteosarcoma cell line, which contains a normal retinoblastoma allele, or the C33A cervical carcinoma cell line that contains a mutant pRB, had no effect. The ability of pRB to reverse the malignant phenotype of tumor cells may depend on what other genetic alterations have occurred in the cell.

4.1 RB Protein Structure

Functional domains of the coding region of pRB were delineated using deletion mutant analysis. The protein is divided into four regions, the N terminus, the A and B domains separated by a spacer region, and the C terminus (Fig. 2). Disruption of growth suppression by pRB requires the A and B domains as well as portions of the C-terminal domain. The nuclear c-Abl protein binds to the C terminus of pRB, promoting proliferation. The C terminus is required for growth suppression along with the A and B domains.

The A/B region of pRB binds to the LXCXE (Leucine-X-Cysteine-X-Glutamic acid, where X is any amino acid) epitope of the viral oncoproteins, simian virus 40 largeT antigen (TAg), adenovirus E1A, and human papilloma virus-16 E7. The importance of the A/B domain is evident by the large number of endogenous proteins binding to it and the number of tumorigenic missense mutations affecting it (Fig. 1). X-ray crystallography shows that the A domain is required for stable folding of the B region, the site of binding of LXCXE proteins. Even when the A and B regions of pRB are expressed on separate proteins, they are able to form a repressor motif that is regulated by phosphorylation. Another highly conserved region is the intervening sequence between the A and B regions, suggesting an additional protein binding site, or a critical role in folding. Indeed, the E2F transcription factor binds to the highly conserved interface between the A and B regions of pRB.

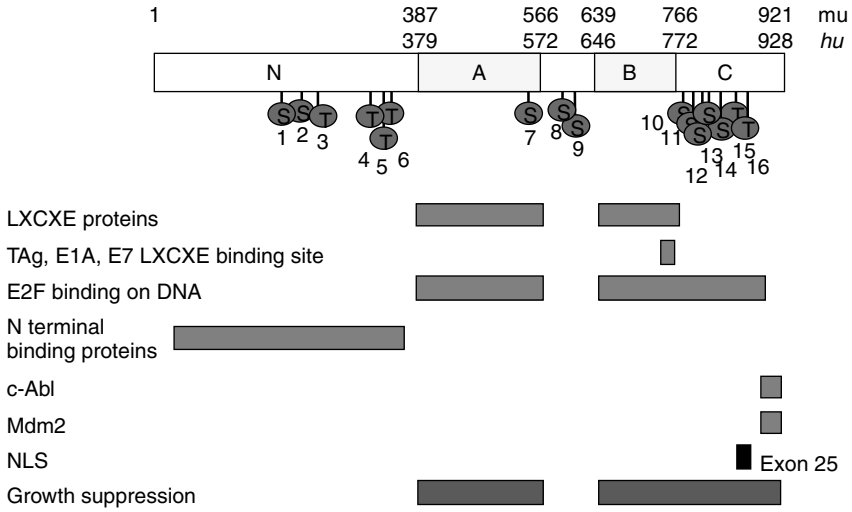

Fig. 2 Structure of pRB. Numbers above the schematic designate the amino acids. Mu corresponds to murine pRB (normal numbers) and hu to human pRB (italics). The N and C termini and the A and B regions are required for binding the SV40 large T antigen. Positions of the 16 phosphorylation sites in murine pRB are shown with S (serine) (red) and T (threonine) (blue). Areas of pRB required for different functions are indicated below the schematic. (See color plate p. xxxiii).

The ability of pRB to enter the nucleus is regulated by a bipartite nuclear localization signal located in the C terminus. The underphosphorylated (active) form of pRB binds the nucleus, following salt extraction, more effectively than the phosphorylated (inactive) form. A/B region mutants are poorly retained in the nucleus, and the A/B region can experimentally translocate a cytoplasmic protein to the nucleus.

4.2 RB Family Members

Two genes/proteins homologous to *RB1*, p107, and p130, which had previously been observed to bind E1A, were identified by sequence comparison. Some antibodies that were developed against pRB also recognized p107 and p130, suggesting structural homology. All three RB family proteins are found in both hypo- and hyperphosphorylated forms. However, while p107 and p130 bind to cyclin A and cyclin E, pRB does not. Cyclin A binds to the A/B spacer region of p107, which is highly conserved between p107 and p130.

The RB family members express differently during the cell cycle. During quiescence, p130 is expressed, but disappears as cells are stimulated to reenter the cell cycle. Quiescent cells do not express p107, but as cells reenter the cell cycle, p107 accumulates. In contrast, pRB levels are generally constant throughout the cell cycle, although there is a small increase in the level of pRB following growth stimulation.

While tumor suppression was defined first by the powerful function of pRB, there is not much evidence that the other RB family members can independently act as tumor suppressors. However, to

some extent, the RB family compensate for each other. Exogenous overexpression of p107 can suppress the growth of C33A cells, which have a mutant pRB, even though wild-type pRB is unable to. Growth suppression in C33A cells by p107 is mediated through its cyclin/cdk binding domain in addition to the A/B and C domains. p130 has been shown to suppress the growth of only one cell line, the human glioblastoma cell line T98G, which is refractory to suppression by pRB or p107. Few mutations of p107 or p130 have been observed in human tumors.

4.3 RB Protein Phosphorylation

One of the first clues to the function of pRB came following the discovery that the phosphorylation status of pRB depends on the cell cycle. pRB is underphosphorylated in G_0/G_1 phase and hyperphosphorylated in the S- and G_2/M phases in all cell types. pRB phosphorylation occurs on serine and threonine residues. No phosphotyrosine is evident. Following mitogenic stimulation, pRB is phosphorylated in three stages during cell cycle entry and progression: mid-G_1-phase, S-phase, and G_2/M (Fig. 3). Dephosphorylation of pRB occurs after the beginning of mitosis, and may be regulated by differentiation signals.

Because of its significance in growth regulation, great attention has been paid to the regulation of pRB by phosphorylation. Large T antigen specifically binds unphosphorylated (active) pRB to transform cells, possibly by releasing cellular-binding proteins. Inactivation of pRB by phosphorylation occurs through the action of the cyclin-dependent kinases (cdks). The cdk family member, $p34^{cdc2}$, was first found to bind to and phosphorylate pRB. The cdc2 kinase is the active subunit of the M-phase promoting factor, which phosphorylates specific serines or threonines in its consensus site Z-S/T-P-X-Z (where X is polar and Z is generally basic). pRB contains 16 potential cdc2 phosphorylation sites, of which at least nine have been shown to be phosphorylated *in vivo* (Fig. 2). Phosphopeptide analysis shows that *in vitro* phosphorylation by cdc2 corresponds to *in vivo* phosphorylation of pRB. However, cdc2 is activated in late G_2-and M-phases and a homologous kinase, cdk2, may first bind to and phosphorylate pRB, consistent with phosphorylation of pRB to promote exit from G_1.

Cdks are activated following binding to cyclins and phosphorylation of a conserved threonine by the Cdk-activating kinase. The expression of cyclins varies during the cell cycle, with cyclin D and E expressed during G_1, cyclin A during S-phase, and cyclin B during mitosis. Cyclins E and A form a functional unit by binding to cdk2 in G_1- or S-phase respectively, whereas cyclin D forms a complex with cdk4 or cdk6 in G_1. Cyclin B binds to cdc2 in late G_2.

While complexes of each of these cyclins can phosphorylate pRB, only cyclins A, D, and E are able to reverse the ability of pRB to block cells in G_1. Although initial reports suggested that phosphorylation of pRB occurred on the same residues whether phosphorylated by cyclin D-cdk4, cyclin E-cdk2, or cyclin A-cdk2 complexes, it is now recognized that different cyclin-cdk complexes regulate different phosphorylation sites, in a collaborative effort to completely inactivate pRB. In yeast, three G_1 cyclins, Cln1, Cln2, and Cln3, regulate the activity of Cdc28 throughout G_1. Mammalian cyclin E is able to substitute for a *cln2* mutant and cyclin D1 for a *cln3* mutant. Phosphorylation of pRB in yeast requires a combination of Cln3 and either Cln1

or Cln2, suggesting that cyclins D and E must collaborate to completely phosphorylate pRB. Study of cyclin D-cdk4/6 and cyclin E-cdk2 kinase inhibitors activities in mammalian cells confirms these results. In U2OS cells, pRB is partially phosphorylated by cyclin D kinase activity, with complete phosphorylation requiring cyclin E activity. Phosphorylation of pRB only by cyclin D kinase did not release pRB from its interaction with E2F1. Continued phosphorylation of pRB on specific sites in S-phase by cyclin A-cdk2 activity may also be important for the completion of DNA synthesis.

pRB is also regulated by another kinase, cyclin C-cdk3, at the G_0/G_1 transition. Phosphorylation of pRB at specific substrate sites is required for cells to exit G_0 efficiently (Fig. 3). Cyclin C directs phosphorylation of pRB in a temporal pattern that precedes pRB phosphorylation by cyclin D or cyclin E complexes. Therefore, cyclin C plays an important role in regulating the G_0-to-G_1 transition in a pRB-dependent manner.

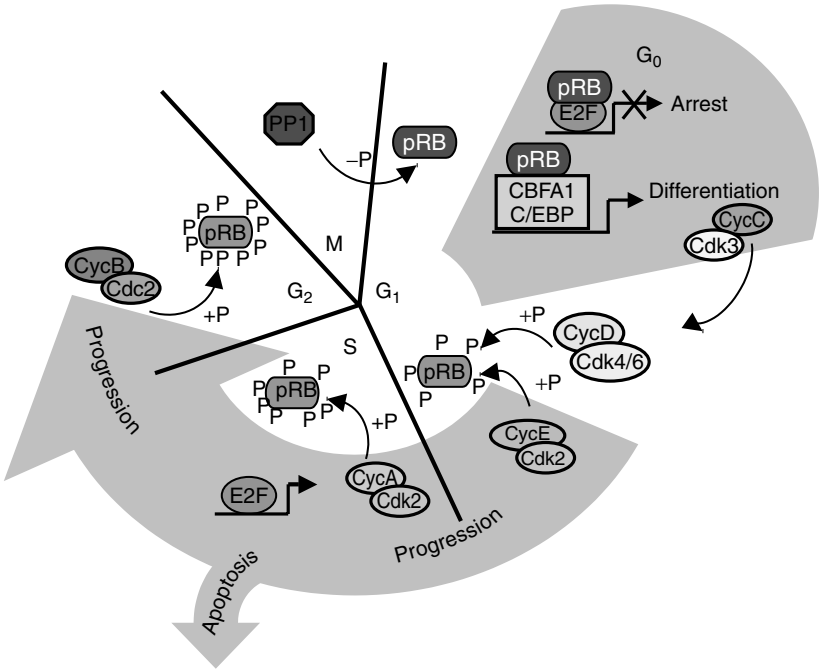

Fig. 3 pRB regulates cell cycle progression, differentiation, and apoptosis. Hypophosphorylated pRB represses genes necessary for S-phase entrance by repressing transcriptional activation by E2F, causing cell cycle arrest, and activates genes necessary for differentiation by binding cell type–specific transcription factors. Phosphorylation of pRB by cyclin C-cdk3 kinase stimulates exit from G_0, and in late G_1 phosphorylation by cyclin D-cdk4/6 and cyclin E-cdk2 kinases releases E2F, allowing cell cycle progression. Continual phosphorylation of pRB occurs by cyclin A-cdk2 and cyclin B-cdc2 complexes in S and G_2 phases. pRB is activated in late mitosis by dephosphorylation. Inappropriate entry into S-phase in the absence of pRB induces apoptosis.

Dephosphorylation (reactivation) of pRB is dependent on the activity of phosphoprotein phosphatase type 1 (PP1), which associates with pRB *in vivo* during mitosis. Microinjection of PP1 into either the nucleus or the cytoplasm of cells synchronized in G_1 increases the resistance of pRB to extraction from the nucleus and correlates with inhibition of S-phase progression.

4.4 RB and E2F Protein Families in Cell Cycle Progression

Viral oncoproteins induce proliferation of mammalian cells by interfering with binding of pRB to cellular proteins. The first such cellular protein to be identified was the transcription factor E2F. The E2F transcription factor regulates the activity of promoters containing an E2F binding site, originally identified as the sequence element in the adenovirus E2 promoter that allowed transcription in mammalian cells. The E2F binding site (TTTSSCGC where S is C or G) has been identified in promoters of genes encoding S-phase-regulatory proteins such as DNA polymerase α, thymidylate synthase (TS), proliferating cell nuclear antigen (PCNA) and ribonucleotide reductase (RR), and cell cycle progression genes such as cyclin A, cyclin E, cdc2, and B-myb. The *E2F1* and *RB1* genes are also regulated by E2F activity, suggesting the existence of an autoregulatory loop in the pRB/E2F pathway. pRB mutants that bind free E2F but do not repress transcription are unable to block S-phase entry. Coexpression of *E2F1* with pRB releases the G_1 block and pushes cells into S-phase. Thus, the primary way that pRB blocks the cell cycle in the G_1-phase is through repression of E2F-responsive genes.

The E2F family of proteins consists of seven members (E2F1, -2, -3, -4, -5, -6, and -7). E2F1-5 proteins each contain a DNA binding domain, a transactivation domain, and a C terminus region that binds pRB or other pRB family members. The ability of E2F proteins to regulate transcription is also dependent on binding to the DP family of proteins. Two mammalian DP proteins bind E2F to enhance interaction with E2F binding sites and activate E2F-responsive promoters. However, not all genes with an E2F site are activated by E2F. *In vivo*, E2F is released from the E2F binding site of the B-myb promoter at the same time that B-myb transcription is activated, suggesting that the E2F complex suppresses this promoter. E2F6 contains neither the transactivation domain nor the C terminus pRB binding region, but represses transcription by complexing with DP proteins to either actively repress or replace other E2F/DP complexes. E2F7 has two DNA binding domains but binds the E2F binding consensus site independently of DP proteins. It too does not have a transactivation domain or the pRB binding region, but functions as a repressor of certain E2F-regulated genes.

Overexpression of E2F1 pushes cells into untimely S-phase, followed immediately by induction of apoptosis. pRB protects cells from apoptosis by complexing with E2F1. However, while a transactivation-defective E2F1 mutant induced apoptosis, a DNA-binding defective E2F1 mutant did not, suggesting that the pRB/E2F1 complex may repress genes necessary for induction of apoptosis.

Different RB family proteins bind E2F family proteins at different phases of the cell cycle. pRB binds E2F1- 4, whereas p107 and p130 bind only E2F4 and 5. E2F4 or 5 are predominantly bound to p130 in quiescent G_0 cells and to p107

in proliferating cells. pRB binds and regulates E2F1, 2, and 3 in G_1 but binds to E2F4 when cells are induced to reenter the cell cycle.

The activity of E2F is also regulated in a cell cycle–dependent manner by degradation of free E2F protein. E2F1 and 4 have C-terminal sequences that target them for degradation via the ubiquitin-proteasome pathway. Binding of pRB to E2F1 or p107 to E2F4 increases the half-life of the E2F protein. Endogenous E2F1 is more stable in G_0/G_1 when bound to pRB than in S-phase. This suggests that the RB family may maintain cells in G_1 by assuring that E2F is present to repress promoters. E2F activity is also stabilized by acetylation. pRB also blocks recruitment of the preinitiation complex to the promoter by E2F.

4.5 Other Binding Proteins

A diversity of action is evident from the large number of proteins that bind to pRB with different functions (Table 1). In addition to E2F, pRB binds a number of general transcription factors (ATF-2 and SP1) and cell type–specific transcription factors (Elf-1, PU-1, MyoD, and NF-IL6). Generally, the binding of pRB represses transcriptional activity; however, binding to factors such as c-Jun, MyoD, C/EBP, and NF-IL6 has a positive effect on differentiation of specific cell types,

Tab. 1 Some of the proteins that bind pRB.

Function	*pRB-binding Proteins*
Cdk inhibitor	p21
Chromatin modulator	BRG1
Chromosome scaffold	H-Nuc
Corepressor	CtIP, RbAp48, RBP1, HBP1
Cyclins	Cyclins D1, 2, 3
Histone deacetylase	HDAC1
Molecular chaperone	hsp75
Nuclear matrix	Lamin A, p84
Phosphatase	PP-1a2
Pol I transcription factor	UBF
Pol II transcription factor	TAFII250
Pol III transcription factor	TFIIIB
Potential tumor suppressor	Prohibitin, BRCA1
Protein kinase	RbK
Regulator of p53 stability	MDM2
Replication licensing factor	MCM7
Ser/Thr kinase	cdc2, cdk2
Signaling molecule	Raf-1
Transcription factor	ATF-2, c-Jun, c-Myc, N-Myc, C/EBP, E2F-1, Elf-1, hBRM, Id-2, MyoD, Myogenin, NF-IL6, PU.1, Sp1, Pax-3, PHox, Chx10, RIZ
Transformation inducer	Bog
Tyrosine kinase	c-Abl
Viral oncoprotein	E1A, E7, Large T Ag
Viral transcription factor	EBNA-5, HCMV IE2

although the precise mechanism(s) of activation is not yet known.

pRB may repress the activity of factors such as E2F1 by recruitment of histone deacetylase (HDAC1) to the promoter. HDAC1 facilitates the formation of nucleosome structures that block access of positive transcription factors to the promoter. In addition, pRB binds a number of corepressors including RbAp48, RBP1, and C-terminal interacting protein (CtIP), which function by directly repressing transcription or by recruiting HDAC1. However, pRB also represses transcription of promoters that are not sensitive to histone deacetylase activity, by unknown mechanisms. Thus, pRB can actively repress transcription factors, block access of transcription factors to basal transcriptional machinery, or directly inhibit the basal transcriptional machinery.

In addition to regulation of polymerase II transcription, pRB regulates polymerase I genes by binding and inhibiting the ability of an upstream binding factor to bind the ribosomal DNA promoter. pRB binds the general polymerase III transcription factor TFIIIB to regulate genes such as tRNA, 5s RNA, and TATA-box containing genes such as U6. Polymerase III transcription is also regulated by binding of p107 and p130 to the BRF subunit of TFIIIB.

The signaling molecule Raf-1 binds pRB within 30 min of serum stimulation, directly linking mitogenic signaling and cell cycle regulation, which may be one mechanism of transducing Ras cell surface signals to the cell cycle. Inactivation of Ras by a monoclonal antibody in $RB1^{+/+}$ cells efficiently inhibits DNA synthesis. In $RB1^{-/-}$ cells, inhibition of DNA synthesis is defective. Thus, pRB is required for cell cycle progression downstream of Ras.

4.6 Differentiation by Retinoblastoma Protein

Cell culture systems have revealed a role of pRB in determining the fate of the cell. pRB positively regulates terminal adipocyte differentiation of murine embryonic fibroblasts by binding to and activating the CCAAT/enhancer-binding proteins (C/EBPs), a family of transcription factors necessary for adipocyte differentiation. When the cell is induced to differentiate, pRB binds to C/EBP. When U937 cells respond to phorbol 12-myristate 13-acetate by differentiation into monocyte/macrophage lineages, pRB binds NF-IL6, another member of the C/EBP family. Production and maintenance of a terminally differentiated muscle cell phenotype requires binding of pRB to MyoD both *in vitro* and *in vivo*. Differentiating human keratinocytes contain pRB/c-Jun complexes that are absent from nonsynchronized cycling cells, in part by facilitating binding of c-Jun to an AP-1 consensus site. In bone development, pRB interacts with an osteoblast transcription factor, CBFA1, resulting in synergistic transactivation of an osteoblast-specific reporter. This finding is significant since osteosarcoma is the second most common tumor after retinoblastoma in $RB1^{+/-}$ individuals, and loss of pRB occurs in 60% of sporadic osteosarcomas, suggesting a bone-specific tumor suppressor function of pRB. These culture experiments are consistent with the idea that differentiation involves activation by pRB of genes that are needed for cell type–specific differentiation.

5
RB Family Regulation of Murine Development

5.1
RB1 in Murine Development

$RB1^{-/-}$ mice show normal early retinal development up to embryonic days (E)13–15, but then die with abnormalities in neurogenesis and erythropoiesis due to placental failure (Table 2). Wild-type trophoblast rescues $RB1^{-/-}$ embryos until birth, when a muscle defect, previously recognized in partial rescue of $RB1^{-/-}$ embryos, is lethal. The cause of early embryonic lethality is excessive proliferation of trophoblast cells and a severe disruption of the normal labyrinth architecture in the placenta, resulting in decreased vascularization and reduction in placental transportation function. $RB1^{-/-}$ mice that are reconstituted with a functionally normal placenta lack many of the phenotypes of $RB1^{-/-}$ mice and show histologically normal dorsal root ganglia, brain, retina, spinal cord, and liver, but they still die at birth or shortly thereafter with marked defects in skeletal muscle and apoptosis of peripheral nervous system and lens.

Tagged $RB1^{-/-}$ cells in the brains of chimeric embryos exhibited extensive S-phase entry. However, unlike the widespread apoptosis in the germline $RB1^{-/-}$ mice, the majority of the $RB1^{-/-}$ cells in the chimera survived and differentiated into neurons. The developing retina of chimeric embryos showed ectopic mitoses and substantial cell degeneration, while the contribution of $RB1^{-/-}$ cells to the adult retina was much reduced. Therefore, in the CNS, cell-autonomous cell cycle regulation is dependent on functional pRB, but neuronal cell survival and fate may be non-cell-autonomous. In the chimeric CNS, an exception was the $RB1^{-/-}$ Purkinje neurons that were lost. Thus, pRB function may be required in a cell-autonomous manner for cell cycle regulation in most tissues but suppression of apoptosis and differentiation may be either cell-autonomous or non-cell-autonomous, depending on the tissue involved. These data suggest that the role of pRB in development and differentiation is more important for some cell types than others.

5.2
p107 and p130 in Murine Development

The importance of the pRB family in differentiation is also demonstrated by $p107^{-/-}$; $p130^{-/-}$ mice, which are viable until birth and show deregulated chondrocyte growth and defective endochondral bone formation (reduced rib cage size and shortened limbs). The importance of each pRB family member may be dependent on the level of expression in a particular cell type, and may also depend on the strain of mouse, suggesting the existence of strain-specific modifier genes. Deletion of *p130* in Balb/cJ mice resulted in embryonic lethality, while the same deletion in C57BL/6J mice produced viable mice with a reduction in the number of spinal cord and dorsal root ganglia neurons and myocytes, and neural tube and brain apoptosis with increased proliferation.

Balb/cJ and C57BL/6J mice lacking *p107* were viable like their counterparts but the Balb/cJ mice displayed impaired growth, reaching only 50% of the weight of their counterparts by 21 days of age. There was also myeloid hyperplasia in the spleen and liver and a twofold acceleration of the cell cycle in $p107^{-/-}$ fibroblasts and myoblasts, suggesting a role for *p107* in negatively regulating the overall length of the cell cycle.

Tab. 2 *RB1* phenotypes in mice.

Mouse	***Phenotype***
No retinoblastoma	
RB1$^{+/-}$	*RB1*$^{-/-}$ pituitary and thyroid tumors
RB1$^{-/-}$	Lethal E13-E15, abnormalities in neurogenesis and erythropoeisis, apoptosis, and inappropriate S-phase entry in CNS, PNS, and lens
RB1$^{-/-}$ with normal placenta	Die at birth with marked defects in muscle and lens, no abnormalities in neurogenesis and erythropoeisis
RB1$^{-/-}$; *RB1*$^{+/+}$ chimeric	Normal, apoptosis of *RB1*$^{-/-}$ cells in retina
NesCre1-Cre; *RB1*$^{loxP/loxP}$	Apoptosis in lens and PNS but not in CNS, inappropriate S-phase entry in CNS, PNS, and lens
IRBP-Cre; *RB1*$^{loxP/loxP}$	Neuroendocrine tumors of the pineal and pituitary gland
p107$^{-/-}$	Normal on C57B/6J, 50% smaller on Balb/cJ
p130$^{-/-}$	Normal on C57B/6J, die at E11.5 on Balb/cJ
RB1$^{+/-}$; *p107*$^{-/-}$	Retinal dysplasia; *RB1*$^{-/-}$; *p107*$^{-/-}$ pituitary and thyroid tumors
RB1$^{-/-}$; *p107*$^{-/-}$	Lethal E11.5
RB1$^{+/-}$; *E2F1*$^{-/-}$	Reduced frequency of pituitary and thyroid tumors, increased life span compared to *RB1*$^{+/-}$ mouse
RB1$^{-/-}$; *E2F1*$^{-/-}$	Lethal E17
RB1$^{+/-}$; *p53*$^{-/-}$	Retinal dysplasia, *RB1*$^{-/-}$; *p53*$^{-/-}$ pituitary and thyroid tumor
RB1$^{+/-}$; *Arf*$^{-/-}$	Accelerated pituitary tumor development compared to *RB1*$^{+/-}$ mouse
RB1$^{-/-}$; *Apaf1*$^{-/-}$	No apoptosis in CNS and lens, reduced apoptosis in PNS and skeletal muscles
RB1$^{-/-}$; *Id2*$^{-/-}$	Survive to term with no defects in neurogenesis and hematopoiesis seen in the *RB1*$^{-/-}$ mice, die at birth with severe reduction in muscle tissue
MMTV-RB$^{\Delta K}$	Dysplasia in mammary tissue, breast cancer
Papillomavirus E7	Apoptosis in the retina
Viral oncoprotein-induced retinoblastoma	
SV40 TAg transgene (retina)	Retinoblastoma, brain tumor
Papillomavirus E7 & E6 transgene (retina)	Retinoblastoma
Papillomavirus E7, p53$^{-/-}$	Retinoblastoma
Chimeric knockout retinoblastoma	
RB1$^{-/-}$; *p107*$^{-/-}$ (chimera)	Retinoblastoma
Targeted RB1$^{-/-}$ *knockout retinoblastoma*	
Pax6α-Cre; *RB1*$^{loxP/loxP}$; *p107*$^{-/-}$	Retinoblastoma
NesCre1-Cre; *RB1*$^{loxP/loxP}$; *p130*$^{-/-}$	Maternal inheritance results in retinoblastoma

The expression of *p107* and *p130* mRNA helps explain some of these data. While *p130* is expressed at very low levels throughout embryogenesis, there is a notable increase in expression in developing bone, which would explain the bone phenotype in the $p107^{-/-}$; $p130^{-/-}$ knockout mice. *p107*, on the other hand, is expressed highly in the heart, lung, kidney, and intestines but there is no detectable phenotype in these tissues in the $p107^{-/-}$ mice. There is also high expression of *p107* in the CNS and liver, which would explain the accelerated apoptosis seen in the liver and CNS in the $RB1^{-/-}$; $p107^{-/-}$ mice compared to $RB1^{-/-}$ mice.

5.3 E2F in Murine Development

pRB's ability to block cell growth has always been associated with its ability to block E2F activity. Therefore, it was hypothesized that the loss of E2F in the mouse should have a profound effect on development. Surprisingly, the E2F1 knockout mouse was viable but highly tumor prone and contained some tissue atrophy. This suggested that E2F1 was not vital for proliferation of all cell types, possibly because the other E2Fs can compensate, but is required to block proliferation in some cells while promoting proliferation in other cells. Of particular interest is the enlargement of the thymus and lymph nodes as a result of lack of E2F1. This expansion is a result of an increase in the number of mature CD4/CD8 cells and appears to be due to a lack of apoptosis, consistent with the role of E2F1 in apoptosis. However, E2F1 appears to be an important target of pRB in the regulation of tumorigenesis and development. The loss of E2F1 in the *RB1* heterozygous mouse resulted in reduced frequency of pituitary and thyroid tumors and increased life span of the $RB1^{+/-}$; $E2F1^{-/-}$ mouse compared to $RB1^{+/-}$ mouse. Loss of both *RB1* and E2F1 in the $RB1^{-/-}$; $E2F1^{-/-}$ mouse resulted in embryonic lethality but the mouse lived longer than the $RB1^{-/-}$ mouse (E17 compared with E13.5), suggesting that some functions of pRB during development occur through E2F1. Loss of DP1 leads to embryonic lethality due to failure of extra-embryonic lineage development, suggesting a role for the pRB/E2F pathway in placental development.

6 Retinoblastoma in Mice

The generation of $RB1^{-/-}$ mice was expected to provide information regarding development of retinoblastoma. However, embryonic lethality in $RB1^{-/-}$ mice precluded studies of later development of the retina. Unlike humans, $RB1^{+/-}$ mice do not develop retinoblastoma but instead develop pituitary tumors in which both *RB1* alleles are inactivated. The extreme sensitivity of developing human retina to loss of *RB1* has stimulated intense efforts to mimic human retinoblastoma in mice. The features of the susceptible retinal cell, when defined, may well be the features shared by cancer-susceptible cells in many tissues.

6.1 Viral Oncoprotein-induced Retinoblastoma

The first transgenic mouse model of retinoblastoma arose when the simian virus 40 large T antigen (TAg), expressed from the human luteinizing hormone beta subunit (LHβ) promoter in order to

produce pituitary tumors, was serendipitously expressed in a specific cell of retina with malignant potential. This transgenic line of mice develops focal bilateral retinal tumors that are very similar to human retinoblastoma, because of high expression of TAg in the retina. Viral oncoproteins such as HPV E7 and SV40 TAg inactivate pRB when they bind the A/B domain of pRB. TAg binds the active, hypophosphorylated, but not the inactive, hyperphosphorylated form of pRB and also inactivates p107, p130, p53, and other proteins. However, expression of TAg or E7 from the retina-specific promoter interphotoreceptor retinoid-binding protein (IRBP) or opsins does not result in tumors like retinoblastoma. However, IRBP-driven HPV E7 results in retinoblastoma in $p53^{-/-}$ mice.

6.2 Chimeric Knockout Retinoblastoma

The retina was normal in both embryonic $RB1^{-/-}$ mice and chimeric $RB1^{-/-}$; $RB1^{+/+}$ mice, and $RB1^{-/-}$ cells contributed to most tissues. However, *RB1*-deficient cells were excluded from the outer and inner nuclear layer of the retina by apoptosis, suggesting that pRB is required during specific stages of postnatal retinal differentiation. While both the $p107^{-/-}$ and $p130^{-/-}$ mice are viable with no retinal dysplasia, loss of *p107* and one copy of pRB in the $RB1^{+/-}$; $p107^{-/-}$ resulted in retinal dysplasia. Although the $RB1^{-/-}$; $p107^{-/-}$ mice die at E11.5, preventing evaluation of the developing retina, loss of both p107 and pRB in the retinoblasts of $RB1^{-/-}$; $p107^{-/-}$ chimeric mice resulted in retinoblastoma. Using expression markers for terminally differentiated retinal cell types, the authors concluded that the retinoblastoma originated in cells committed to the amacrine cell compartment of the inner nuclear layer (INL) but not in cells committed to the outer nuclear layer (ONL).

6.3 Targeted $RB1^{-/-}$ Knockout Retinoblastoma

Conditional inactivation of *RB1* by expression of Cre recombinase in IRBP-expressing photoreceptor cells (IRBP-Cre; $RB1^{loxP/loxP}$ mice) failed to cause retinoblastoma, even when *p107* and *TP53* were also inactivated. Conditional inactivation of *RB1* by expression of Cre from the Pax6α enhancer in $p107^{-/-}$; $RB1^{loxP/loxP}$ mice resulted in ectopic proliferation of all retinal precursors but only the precursors of horizontal, amacrine, and Müller glia cells survived and terminally differentiated. The Pax6α enhancer is active in peripheral retinal progenitors at E10. Sixty-eight percent of these mice developed tumors in the peripheral retina as early as P8, with larger tumors filling the vitreous at later stages. Markers for amacrine (NeuroD and Math3) and Müller glia (Hes5) were present in the P8 tumor, with few markers for photoreceptor (Crx), bipolar (Chx10), and ganglion cells (Brn3B). P30 tumors expressed markers for amacrine (NeuroD, Math3, Pax6, syntaxin, and calretinin) and Müller glia (Hes5, GFAP, and CRALBP) only.

Conditional inactivation of *RB1* by expression of Cre from the *nestin* promoter (*NesCre1*) results in mosaic expression of Cre through all layers of the retina with maternal NesCre1 inheritance. Breeding these mice with p130 knockout mice resulted in retinoblastoma tumor formation in five out of

five mice, of which four developed bilateral retinoblastoma. The tumors expressed amacrine markers (syntaxin and calretinin) and a few Müller glia cells (GFAP expressing) were also present. However, no tumor stained for the photoreceptor-specific gene IRBP, the bipolar cell marker protein kinase C-α (PKC-α), or the retinal ganglion cell marker Brn3b. A potential amacrine cell origin of these mouse tumors is consistent with the earlier mouse model. However, these mouse tumors contain Homer–Wright rosettes but not the classical Flexner–Wintersteiner rosettes pathognomonic of human retinoblastoma, nor any evidence of photoreceptor differentiation.

Examination of the tumor for markers may define some features of the cell of origin, but may be misleading: progenitor cells destined to follow a pathway that is dependent on pRB may adopt a different fate in the absence of pRB. Retinal progenitors go through a series of changes in intrinsic properties that control their competence to make different cell types. If a pRB-related pathway is disturbed, a cell may follow a default pRB-independent pathway, defined by extrinsic cues from their neighbors. This could explain why the majority of human retinoblastomas show characteristics of photoreceptors (Flexner–Wintersteiner rosettes), while much evidence suggests that they originate in the INL and not in the ONL.

The timing of inactivation of *RB1* may play an important role in the development of retinoblastoma. Unlike adult mice, pRB is expressed in all retinal cells at different times during development. Therefore, loss of pRB at different developmental times could result in different retinal phenotypes. This could explain why mice expressing TAg from two different promoters necessary for photoreceptor development have different phenotypes (no tumors with the opsin promoter versus the entire photoreceptor layer developing tumors with the IRBP promoter).

7 RB Protein and Apoptosis

Among the diverse functions of pRB is the ability to protect cells from apoptosis. $RB1^{-/-}$ embryos die at E13.5 with apoptosis in the CNS, PNS, lens, and other tissues, but rescue of these mice by a normal placenta allows the animals to survive to birth, when a muscle defect is lethal. Similarly, $RB1^{-/-}$; $Id2^{-/-}$ mice show no defects in neurogenesis and hematopoiesis, but die at birth from severe reduction in muscle tissue. Id2 plays a role in regulating cell death in differentiated neurons, and may also protect against the loss of *RB1* in placenta.

Comparison of $RB1^{-/-}$; $p53^{-/-}$ double knockout mice with $RB1^{-/-}$ mice show that the CNS and lens apoptosis are p53 dependent. However, the apoptosis in the PNS was p53 independent. Cells in the CNS of the $RB1^{-/-}$; $p53^{-/-}$ mouse continue to ectopically enter S-phase but do not die. The *p53*-dependent cell death in the CNS but not the lens is due to hypoxia as a result of defective erythropoiesis. However, conditional knockout of *RB1* in the CNS, PNS, and lens in the presence of normal erythropoiesis show similar levels of apoptosis in the PNS and lens compared to the $RB1^{-/-}$ mice, suggesting that the apoptosis in these tissues is a direct result of *RB1* loss. The *NesCre1* mice with *RB1* knockout only in retina show high levels of *p53*-independent retinal apoptosis in late development.

Deregulated expression of E2F1 in fibroblasts results in S-phase entry followed by apoptosis, which is blocked by expression of high levels of pRB. Apoptosis induced following loss of pRB is dependent on the activity of E2F1, since apoptosis does not occur in the lens of the double knockout *RB1*$^{-/-}$; *E2F1*$^{-/-}$ mice. Additionally, mutant mouse embryos lacking E2F3 and *RB1* survive longer than the *RB1*$^{-/-}$ mice and display a significant reduction in apoptosis and inappropriate S-phase entry.

E2F1 induces cell death in a p53-dependent manner by increasing the stability of the p53 protein. In part, this is due to transcriptional activation of $p14^{ARF}$ ($p19^{ARF}$ in mouse), which promotes the rapid degradation of MDM2 in MDM2-p53 complexes, blocking the degradation of p53 by MDM2. However, p53-dependent apoptosis in the lens of the *ARF*$^{-/-}$; *RB1*$^{-/-}$ mice is only partially suppressed and p53-dependent apoptosis and inappropriate S-phase entry in the CNS are similar to that in *RB1*$^{-/-}$ mice.

E2F1 also induces transcription of the p53 homolog, *p73*, which can induce apoptosis. A dominant negative p73 mutant can suppress E2F1-induced apoptosis in cells lacking p53. Additionally, E2F1-induced apoptosis is severely impaired in *p73*$^{-/-}$ MEFs. Another transcriptional target of E2F1 is *APAF1*, which plays an important role in stress- and oncogene-induced apoptosis. Levels of *APAF1* are increased in *RB1*$^{-/-}$ mice, and apoptosis in *APAF1*$^{-/-}$ MEFs is impaired in response to increased E2F1 activity. Analysis of *RB1*$^{-/-}$; *Apaf1*$^{-/-}$ mice shows that *APAF1* is absolutely required for the apoptosis in the CNS and lens of the *RB1*$^{-/-}$ mouse, but only partially rescues the apoptosis in the lens and muscle.

The transactivation domain of E2F1 plays a role in p53-dependent apoptosis but not in p53-independent apoptosis. E2F1 may also play a role in p53-independent apoptosis. Transcriptionally impaired E2F1 mutants induce apoptosis in Saos2 cells, which lack p53 and pRB, while a DNA-binding defective mutant fails to induce apoptosis. The p53-independent induction of apoptosis by E2F1 can be inhibited by direct binding of pRB to E2F1, but is not inhibited by MDM2. Thus, induction of p53-independent and p53-dependent apoptosis by E2F1 occurs through different mechanisms: p53-dependent apoptosis may rely on relief from repression of promoters and p53-independent apoptosis may involve transcriptional activation by E2F1.

pRB may also protect cells from p53-independent apoptosis induced by ionizing radiation, transforming growth factor β1 (TGF-β1), and γ-interferon (IFN-γ). Following DNA damage, cells can arrest in both G_1/S and G_2/M phases of the cell cycle. pRB is required for the G_1/S phase arrest but not for the G_2/M phase arrest. This phenomenon is characteristic of pRB alone. The other members of the pRB family are not able to block cells in G_1/S following DNA damage.

8 Additional Genomic Changes in Retinoblastoma

8.1 Genomic Gains and Losses

Although mutation of both copies of the *RB1* gene is required for formation of retinoblastoma, all retinoblastoma tumors have additional genetic alterations. There is no evidence that any gene besides *RB1*

initiates retinoblastoma; however, other genomic changes may be required for full malignant transformation. Karyotypic analysis and comparative genomic hybridization (CGH) show genomic gains and losses in retinoblastoma tumors. The minimal regions most frequently gained are 1q31 (52%), 6p22 (44%), 2p24-25 (30%), and 13q32-34 (12%) and the minimal region most frequently lost is 16q22 (14%). Some evidence suggests that gains at 1q, 2p, and loss of 16q are restricted to more advanced tumors in older children, possibly correlating with tumor progression. Almost unique to retinoblastoma is a specific pattern of 6p gain, i(6p), identified in 60% of retinoblastoma tumors. This marker chromosome results in four copies of genes on chromosome 6p, or in low-level amplification. The gains and losses may point to potential oncogenes or tumor suppressor genes necessary for progression to malignant retinoblastoma. Identification of these cancer genes is important as they may form the basis of therapy to prevent the progression of small retinoblastoma tumors.

8.2 Candidate M3-Mn Genes

Narrowing the region of 6p gain to a minimal 0.6-Mb region of 6p22 using quantitative multiplex polymerase chain reaction (QM-PCR) for sequence-tagged sites (STS) identified RBKIN, a novel human kinesin-like gene, as a potential oncogene in retinoblastoma. RBKIN expression is increased in retinoblastoma compared to normal human retina, and inhibition of RBKIN in retinoblastoma cell lines using antisense oligonucleotides blocks cell proliferation, consistent with a role for RBKIN as an oncogene. Chromosome 6p gain is also common in bladder cancer and is associated with an elevated risk of progression.

Cadherin-11 (CDH11) was identified as a potential tumor suppressor gene using LOH and QM-PCR to define the minimal region of 16q22 genomic loss in retinoblastoma. The intact form of CDH11 is either completely lost or decreased, while the variant form is present in 50% of retinoblastoma. CDH11 is a cell adhesion molecule whose loss may promote progression of some $RB1^{-/-}$ retinal cells to malignancy. Unusually low levels of the intact form of CDH11 are present in osteosarcoma, while the variant form was highly expressed in invasive breast cancer and was associated with promotion of invasiveness.

8.3 Causes of Drug Resistance in Retinoblastoma

Ling and coworkers first described the multidrug resistance (MDR) phenotype in human cancer, due to upregulation of the *MDR1* gene with increased expression of P-glycoprotein. P-glycoprotein expression is increased in response to environmental toxicity in many organisms, and broadly reduces intracellular levels of vinca alkaloids (vincristine, vinblastine), epipodophyllotoxins (etoposide, teniposide), and other natural-product antineoplastic agents by functioning as an ATP-dependent plasma membrane pump that expels drugs from human cancer cells. Platinum compounds are not substrates of the P-glycoprotein drug efflux mechanism.

Expression of *MDR1* in retinoblastoma at initial diagnosis and increased expression at relapse after failed treatment may account for frequent chemotherapy failures. It is not possible to correlate P-glycoprotein levels before therapy with the

outcome of chemotherapy in intraocular retinoblastoma, since biopsies incur risk of systemic spread. In metastatic retinoblastoma, P-glycoprotein expression before therapy correlates with failure of therapy, and initially undetectable P-glycoprotein correlates with long-term remission.

In order to save eyes without radiation, which increases the lifelong risk of secondary malignancies and other long-term side effects, chemotherapy has become the primary therapy for intraocular retinoblastoma in many centers worldwide. One protocol with excellent success to cure eyes without use of radiation or removal of the eye includes a direct approach to counter P-glycoprotein MDR. High-dose cyclosporine A (CSA) is delivered simultaneously with the chemotherapy to block the ability of P-glycoprotein to protect tumor cells from chemotherapy. An international Phase II Clinical Trial of CSA-modified chemotherapy is underway.

Intraocular retinoblastoma that failed chemotherapy without CSA showed increased P-glycoprotein when examined by immunohistochemistry. Retinoblastoma that failed chemotherapy despite administration of CSA did not express P-glycoprotein but expressed instead the Multidrug Resistance Protein (MRP). MRP belongs to the same ATP-dependent membrane transporter superfamily as P-glycoprotein, and transfection of the MRP gene confers a similar broad-spectrum pattern of drug resistance to antineoplastic agents. Although CSA inhibits P-glycoprotein *in vitro*, there is presently no effective inhibitor of MRP.

Several chemotherapy drugs induce apoptosis in $RB1^{-/-}$ cells and growth arrest in $RB1^{+/-}$ cells. It is proposed therefore that continued expression of pRB in some tumors may contribute to drug resistance. These drugs might selectively destroy $RB1^{-/-}$ tumors, while pRB-expressing adjacent normal cells might be protected by pRB.

9 Importance of Retinoblastoma

The rare eye cancer, retinoblastoma, continues to contribute much more than its "share" to understanding of cancer, biological processes, and use of scientific knowledge to optimize health outcomes. *RB1* is the first tumor suppressor gene discovered and revealed the process (search for loss of heterozygosity) that was used to discover other genes underlying human cancer. The RB gene family members are key cell cycle regulators, so that their mutation alters development and deregulates the cell cycle to induce cancer in susceptible cells. The many ways that *RB1* can be damaged and the high mutation rate have forced creative technology development to meet the challenges of clinical diagnostics, much of which has been widely generalized to other genetic disease challenges. At a health service level, it is clearly shown that molecular determination of individual *RB1* mutant alleles contributes importantly to health quality at less cost.

Analysis of genetic changes in retinoblastoma subsequent to loss of both *RB1* alleles has revealed several potential novel genes involved in tumor progression and resistance to therapy, which will clearly become the targets for potential prevention and therapeutic strategies. Recognition of the key role of the *MDR* gene in retinoblastoma provided the rational basis for a therapeutic strategy to counter drug resistance that appears to improve the cure rate of intraocular retinoblastoma and

that is currently the basis of an international multicenter clinical trial. Although basic studies clearly show an important role of *MDR* in many cancers, only in retinoblastoma has a therapeutic strategy to alter *MDR* effect shown positive clinical outcome.

Much more is yet to come. The focus on defining the unique features of the exact cell in developing human retina that is susceptible to cancer by loss of pRB is key to understanding ''cancer stem cells.'' Retinoblastoma is one of the best examples of human disease indicating that only rare cells at a specific developmental and proliferative stage may be at risk to initiate tumors. And the rarity of retinoblastoma has been turned again to advantage by the world participation of major retinoblastoma treatment centers in an Internet survey to validate a new clinical classification, showing that global cooperation can reach out to future optimal opportunities for all families afflicted with this rare, unique cancer.

Phototransduction
The sequence of biochemical reactions that are initiated by the photoisomerization of rhodopsin and lead to the hyperpolarization of photoreceptor membranes.

Retinal Pigment Epithelial Cells (RPE)
Epithelial cells that are anatomically placed behind the photoreceptors in the eye. Virtually all of the biochemical reactions in the visual cycle occur in the RPE.

Retinoids
Diterpene polyene derivative in the vitamin A family that includes all-*trans*-retinol (vitamin A), all-*trans*-retinal, all-*trans*-retinyl esters and their 11-*cis*-congeners.

Visual Cycle
The biochemical pathway that begins with the photoisomerization of the 11-*cis*-retinal Schiff base chromophore of rhodopsin to all-*trans*-retinal and ends with the resynthesis of 11-*cis*-retinal.

In the 1930s, Wald discovered that the photoconversion of 11-*cis*-retinal to all-*trans*-retinal is the primary event in vision. Vision would be a once in a lifetime event if the 11-*cis*-retinal chromophore of rhodopsin were not resynthesized. In this review, the biosynthetic pathway through which vitamin A is transformed into the visual chromophore is described.

1 Introduction

Light perception in all sighted animals depends on a photoisomerization event of a derivative of the retinoid vitamin A. The photoisomerization reaction in question is the *cis* → *trans* isomerization of the 11-*cis*-retinal Schiff base (the chromophore) of rhodopsin into its all-*trans* congener (Fig. 1). This simple double-bond isomerization reaction in the retinoid polyene underlies human vision. As vision proceeds, the all-*trans*-retinal photoisomerization product must be enzymatically reisomerized into 11-*cis*-retinal in order for vision to continue. This turns out to be by far the most intricate and complicated chemical process found in all of retinoid biology. The chemical process through which an all-*trans*-retinoid is isomerized into an 11-*cis*-retinoid is the subject of this review.

The vertebrate visual cycle is comprised of those biochemical reactions that begin with the photoisomerization/hydrolysis of the 11-*cis*-retinal Schiff base chromophore of rhodopsin in the photoreceptors to all-*trans*-retinal, and ends with the processing of all-*trans*-retinyl esters (tREs) in the retinal pigment epithelium (RPE) to form 11-*cis*-retinol (al) (cROL(AL))(Fig. 1). The bleaching of rhodopsin to initiate

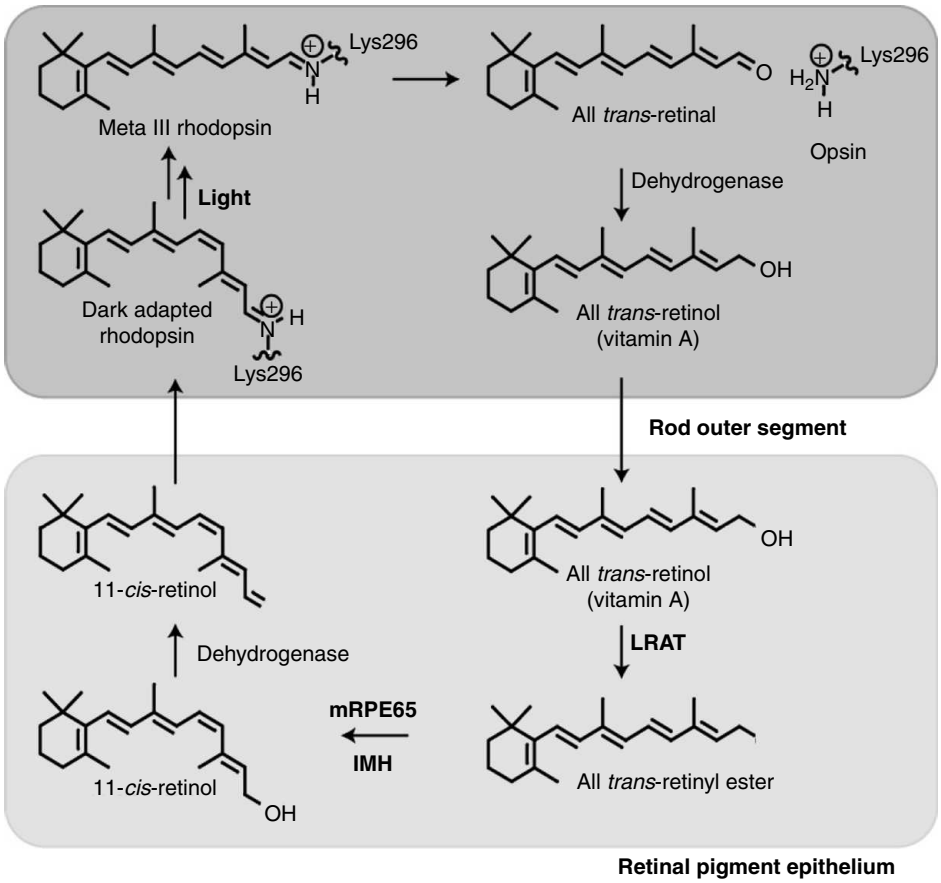

Fig. 1 The visual cycle. The critical retinoid isomerization process is carried out by a three-component system comprised of LRAT, mRPE65, and IMH, which is located in the retinal pigment epithelium.

the phototransduction cascade has been intensively studied over the years. The key event here is the photochemical *cis–trans* photoisomerization, leading to the functionally active conformer(s) of rhodopsin (Meta II). Meta II initiates the cascade of biochemical events leading to photoreceptor hyperpolarization.

Since the photoisomerization/hydrolysis of the 11-*cis*-retinal Schiff base chromophore to all-*trans*-retinal is irreversible at low levels of illumination, biochemical processes must be in place to resynthesize 11-*cis*-retinal in the dark from an all-*trans*-congener. A limitation on any mechanism postulated for regeneration is the fact that 11-*cis*-retinoids are thermodynamically unstable, accounting for only one part per thousand in an equilibrium mixture of retinoids. Thus, an energy source must be posited for the enzymatic *trans-cis* isomerization required in the biosynthesis of 11-*cis*-retinol. This thermodynamic constraint is central to any mechanism forwarded concerning the operation of the visual cycle.

2 Overview of Isomerization Pathway

A central issue in the operation of the visual cycle to address is the nature of the isomerization substrate. Studies of this type required an *in vitro* system capable of producing 11-*cis*-retinoids from all-*trans*-retinoids. The first *in vitro* system able to enzymatically process an all-*trans*-retinoid to an 11-*cis*-retinoid was established in 1987. It was shown that all-*trans*-retinol (vitamin A) (tROL) added to the retinal pigment epithelial cells (RPE) is converted into tREs (chiefly palmitate) and to cROL (al) and esters. The studies established that the RPE contained the biochemical machinery required for the processing of tROL into 11-*cis*-retinoids. In rod-dominated eyes, the only biochemical reaction known to occur in the photoreceptors is the reduction of all-*trans*-retinal (tRAL) into tROL. After the tROL is transported across the interphotoreceptor space, probably by the binding protein interphotoreceptor retinol-binding protein (IRBP), the remaining enzymatic processing to cRAL occurs in the RPE. The visual chromophore, cRAL, is returned to the photoreceptor, again probably bound to IRBP, where it is able to regenerate rhodopsin from opsin. It should be noted that all discussions here are concerned with rod regeneration, although it is clear that cone light independent regeneration obeys the same molecular logic found in rod regeneration.

Since all-*trans* and 11-*cis*-retinoids exist as retinols, retinals, and retinyl esters, it is not immediately obvious what the substrate and product of isomerization are; nine possible routes formally exist. To simplify analysis, double labeling experiments with 15-^{3}H, 15-^{14}C-tROL were performed. If isomerization occurred through the retinal as an intermediate, then the product of isomerization should lose one-half of its ^{3}H. The results are clear-cut and showed minimal loss of ^{3}H during isomerization, demonstrating that isomerization occurs at the alcohol level of oxidation. This leaves four possible isomerization routes, with retinyl esters and alcohols being possible isomerization substrates and products.

Retinyl esters are generated in the RPE by lecithin-retinol acyltransferase (LRAT), which catalyzes the reversible esterification of tROL using lecithin (phosphatidylcholine) as the acyl donor (Fig. 2). The transfer occurs specifically from the *sn*-1 position of lecithin, producing a retinyl ester and a lysophospholipid as products. This is the only known route of retinyl ester synthesis in RPE membranes. It should be noted that LRAT had been identified, not by traditional enzyme purification techniques, but by using specific affinity-labeling agents, such as all-*trans*-retinyl bromoacetate (tRBA) and *N*-Boc-L-biocytinyl-11-aminoundecane chloromethyl ketone (BACMK) (Fig. 2). LRAT, a minor membrane-bound protein, proved to be exceedingly difficult to fully purify. While the protein could be readily solubilized, it rapidly loses activity during a variety of purification schemes. In order to actually identify LRAT, the procedure of biotin affinity labeling was used. In this method, a biotin moiety is incorporated into a specific affinity-labeling agent directed toward a particular target protein(s). The enormous affinity and specificity of avidin–biotin interactions were used both to detect the labeled protein on gels and to purify the protein. In the particular instance discussed here, biotin is attached to a tRBA-like molecule (BACMK) and

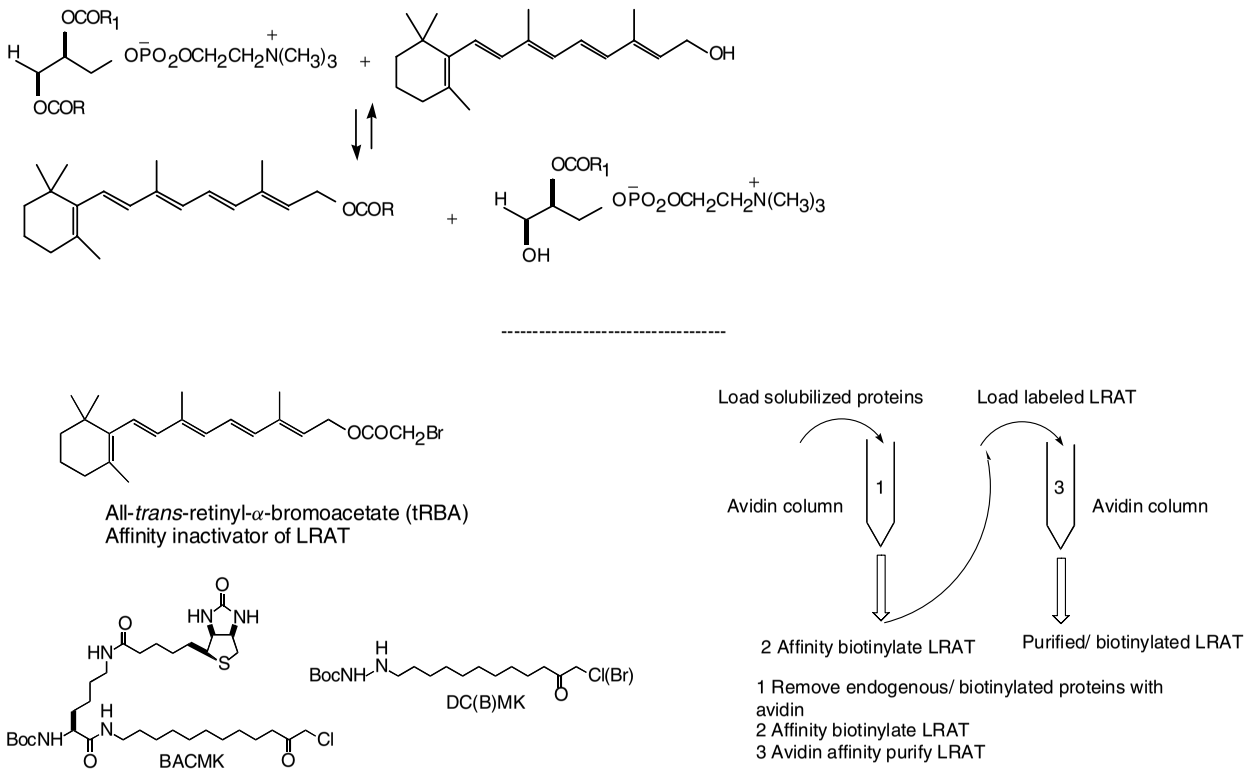

Fig. 2 The standard LRAT reaction and the successful strategy for its purification using specific affinity-labeling reagents.

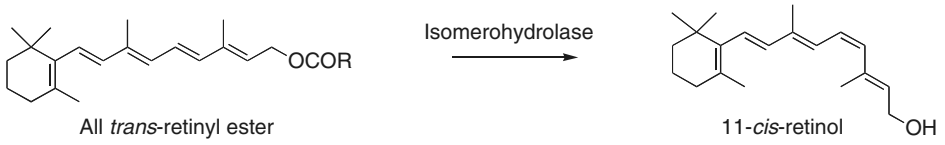
the partially purified protein is specifically labeled (Fig. 2). Using Avidin chromatography, it was possible to obtain enough biotinylated protein to carry out partial sequence analysis. This partial sequence analysis showed that LRAT is a novel protein. This enabled the cloning and expression of human LRAT. LRAT has also been studied kinetically and mechanistically. Interestingly, LRAT is the founder member of a new family of proteins, which include class II tumor suppressors, viral proteases, and a protein that mediates morphogenesis.

As mentioned above, highly specific irreversible enzyme inactivators of LRAT have been designed and they alkylate the active-site cysteine residue of LRAT (C161). These inactivators have been essential for sorting out the substrate and product of isomerization. Two of these inactivators, BACMK, alluded to above, and (tRBA) are shown in Fig. 2. The use of tRBA as a specific inactivator of LRAT in RPE membranes revealed the substrate for isomerization and its product. First, pretreatment of RPE membranes with tRBA abolishes both tRE synthesis and 11-*cis*-retinoid biosynthesis. However, if tRE synthesis is allowed to occur first from tROL, before the applications of tRBA to block LRAT, cROL formation occurs as before. This means that isomerization occurs via an isomerohydrolase (IMH), which converts tREs into cROL. The isomerohydrolase reaction is shown in Fig. 3. The teleological reason for this unusual route is that it allows for the coupling of the free energy of hydrolysis of acyl esters to the thermodynamically uphill *trans* to *cis* isomerization. This unusual process of coupled isomerization/hydrolysis (IMH) for cROL biosynthesis in the RPE has been independently verified using different approaches. Moreover, recent studies on an LRAT knockout mouse are completely consistent with the earlier biochemical experiments and show that tRE synthesis is essential for 11-*cis*-retinoid generation. While these mice have tROL in the RPE, they cannot make 11-*cis*-retinoids. This is exactly what one would predict because tREs are the isomerization substrates. If there were a tROL isomerase, then the knockout animals would have synthesized cROL from it.

The studies described above identify two of the three known elements in the minimally three-component system required for the biosynthesis of cROL in the RPE, namely, LRAT and IMH. Of course, other elements are important as well in the full visual cycle. A specific RPE membrane–bound dehydrogenase (cROL dehydrogenase) carries out the oxidation of cROL to the visual chromophore cRLA. A stereospecific cROL(AL)) binding protein cellular retinaldehyde–binding protein (cRALBP) is also found in the RPE. *In vitro* studies show that this protein kinetically facilitates isomerohydrolase (IMH) action. Since the same result can be achieved with bovine serum albumin, a decidedly nonstereospecific retinoid-binding protein



All *trans*-retinyl ester

11-*cis*-retinol

Fig. 3 Isomerohydrolase reaction.

(RBP), specific interactions with cRALBP are not essential for isomerization. It has been established that 11-*cis*-retinoids inhibit IMH so that the interaction of these retinoids with binding proteins promote isomerization by removing the 11-*cis*-retinoids. cRALBP knockout studies in mice also show that while cRALBP (−) mice appear to undergo rhodopsin regeneration more slowly than WT, the knockouts still regenerate rhodopsin, suggesting an important kinetic, although not essential, role for cRALBP in rhodopsin regeneration. In addition to cRALBP, several other RBPs are known to operate in the visual cycle and are important for its function. None of these RBPs bind the highly hydrophobic tREs, which brings up the question as to how these molecules are mobilized for processing by IMH.

RPE65 plays a central role in tRE binding, mobilization, and processing. RPE65 is a major protein expressed in the retinal pigment epithelium (RPE). This protein, first discovered in 1991, plays an important role in visual cycle function. This conclusion arises from knockout studies in mice, which show that RPE65 knockouts are unable to substantially produce 11-*cis*-retinoids, but accumulate hydrophobic tREs. RPE65 is not IMH and has also not been shown to possess any other enzymatic activity. While RPE65 shows very strong sequence homology to β-carotene-15, 15′ dioxygenase, an enzyme that oxidizes β-carotene into tRAL, RPE65 does not show this enzymatic activity. However, the fact that RPE65 and β-carotene dioxygenase are strongly homologous, suggests the possibility that RPE65 may be a RBP. Studies in this laboratory using retinoid-based affinity biotinylation of RPE65 have demonstrated a tRE-binding ability for RPE65. These experiments reveal that RPE65 is an RBP specific for tREs. This study was followed up with quantitative fluorescence measurements, which further revealed that the membrane-associated form of RPE65 (mRPE65) stereospecifically and saturably binds all-*trans*-retinyl palmitate (tRP) with a 47-nM Kd. tROL is only weakly bound, as are 11-*cis*-retinoids. These studies leave little doubt that mRPE65 is a tRE-binding protein.

As mentioned above, RPE65 knockout mice inappropriately accumulate tREs in oil droplets. REs are exceedingly hydrophobic, with little solubility in aqueous solutions. This can easily be seen in measurements of intermembranous transfer of retinoids. While retinol (al) undergo interliposomal transfer at exceedingly rapid rates, REs are inert to transfer. This would suggest that REs might require binding proteins to mobilize them if they are to productively enter the visual cycle. Since binding proteins are required stoichiometrically, they are required in substantial quantities. The substantial level of RPE65 in RPE membranes, coupled with its ability to bind tREs, suggests the possibility that mRPE65 might have a role in binding to and mobilizing tREs for processing in the visual cycle by IMH. Functional experiments leave little doubt that the role of mRPE65 in the visual cycle is to specifically bind to and mobilize tREs so that they can be processed by IMH. This conclusion suggests a minimally three-component system as the *sine qua non* of visual-pigment regeneration (Fig. 4). In the next section, the chemical biology of the individual components is discussed.

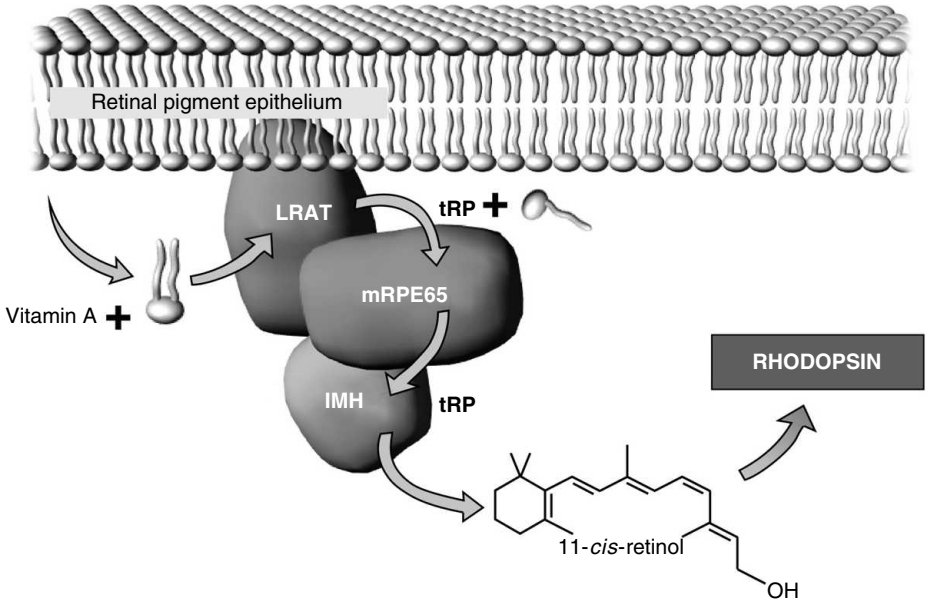


Fig. 4 The three-component system required for 11-*cis*-retinal biosynthesis.

3 Individual Components of the Three-component System

3.1 Lecithin Retinol Acyltransferase

The discovery of LRAT led to an appreciation of the fact that it is a novel enzyme, which, at the time of its discovery, was unrelated to other enzymes of known function. Initial experiments on the enzyme were directed toward mechanistic studies inasmuch as these studies reveal the mechanistic class to which LRAT belongs. Given the nature of LRAT's function as a catalyst of a transesterification reaction, it is likely that the enzyme contains an active-site nucleophile. Initial site-specific mutagenic experiments focused on the four cysteine residues found in human RPE LRAT as candidates. These experiments revealed C161 as the most likely candidate for a catalytically essential active-site cysteine residue. Further experiments were directed at the elaboration of the remaining catalytically essential amino acid residues of LRAT.

3.1.1 C161, H60, and Y154 as a Catalytic Triad in LRAT Action

As described above, LRAT has putative active-site cysteine and histidine residues. Because of this, it is possible that LRAT might operate via a cysteine protease-like mechanism. LRAT shows two pKa's in the pH versus rate profile at pH = 8.3 and 10.8. This however contrasts with thiol proteases, which generally show pKa's of 4.0(abnormal Cys) and 8.5(His). Therefore, it was of substantial interest to determine in what sense LRAT might be included in a thiol protease type family. Figure 5 shows a partial multiple sequence alignment for the LRAT family, in which one can see that the C161 of LRAT is conserved in the remaining family. In

Fig. 5 Partial sequence alignment of LRAT family[a] sequence homology of LRAT family. Multiple sequence alignment of LRAT family was performed by using CLUSTAL W 1.82(http://www.ebi.ac.uk/clustalw/). Fully conserved His, Tyr, and Cys are in red. Accession numbers are as follows: human LRAT (GP:AF 071510), bovine LRAT (GP:AF 275344), mouse LRAT (GP:AF 255061), rat LRAT (GP:AF 255060), mouse Hrev107 (AAH24581), rat Hrev107 (X76453), human Hrev107-3 (P53816), tazarotene-induced gene protein (TIG3) (AF060228), echovirus23, human parechovirus1 (L02971), human parechovirus2 (AJ005695), Avian-encephalomyelitis-virus (AJ225173), EGL26 (NP493652), Aichivirus (AB010145). H60, Y154, and C161 are in red (see color plate p. xxxvi).

addition, though, H60, but not H57, is also conserved. Further experiments on site-specific mutagenesis on LRAT were performed using the readily expressible truncated lecithin-retinol acyltransferase (tLRAT), in which the N- and C-terminal transmembrane domains are removed to increase the solubility of the enzyme. In these experiments, it was clearly revealed that H60 is an essential histidine residue in the LRAT mechanism. In addition, to further explore whether LRAT might be a member or closely associated with the histidine-dependent protease family, it was also determined whether there are catalytically essential aspartate or glutamine residues in tLRAT. These two amino acids often show up as being important for thiol protease catalysis. However, of the glutamine and aspartic acid residues in the LRAT family, only Gln177 and Asp67 are largely conserved in the homologs. We studied the largely homologous aspartate and glutamine amino acids in tLRAT to

determine if they are essential for catalysis. The mutants produced were D49N, D67A, D76N, D111N, D128N, D191N, Q177E, and Q177S (92). The results of these experiments demonstrated unequivocally that neither the aspartate nor glutamine residues are essential for LRAT catalysis.

As mentioned above, we also show that H60 is the essential histidine of LRAT. Previous studies had strongly suggested that C161 is the active-site cysteine. To prove this beyond a shadow of a doubt, tLRAT was inactivated with (3-(*N*-Boc-lys-(biotinyl-0-)-all-*trans*-retinyl chloroacetate (BRCA), a specific inactivator designed for studying tRE binding proteins. The structure of this analog is shown in Fig. 6, compound 1. This analog is a pseudo first-order specific affinity-labeling agent for LRAT and also has the advantage of containing a biotinyl residue, which allows for the tryptic cleavage of the labeled protein followed by the ready purification of the labeled peptide. Moreover, because it has base cleavable ester moieties, the labeled peptide can easily be eluted from an Avidin column by simply raising the pH to 11, thereby generating the active-site peptide labeled with a carboxymethylene moiety. This easily identifies C161 as the active-site nucleophilic group of LRAT. Therefore, C161 is unequivocally the active-site nucleophile, as determined both by site-specific mutagenesis experiments and affinity-labeling experiments. In addition, H60 is the essential histidine residue in the LRAT family of proteins.

An important issue related to the role of C161 in catalysis is to identify the two pKa values found in the pH versus rate profile for LRAT. As mentioned before, there are two pKa values of approximately 8 and 10 observed in the pH versus rate profiles for LRAT. In the tLRAT series, the operant pKa's are 8.22 and 9.95 as compared to 8.5 and 10.4 in full-length LRAT. On the basis of known ionic equilibria, it is assumed that the pKa of approximately 8 is ascribable to C161. However, it is also known that amino acid residues at the active sites of enzymes may have pKa values that are markedly different from those of the amino acids themselves in solution. Therefore, to determine whether C161 is responsible for the pKa ~8, we carried out the pH versus rate profile for the titration of tLRAT with BRCA to determine whether C161 is responsible for the pKa of 8 in LRAT. When the titration of tLRAT was carried out with BRCA, a pKa value of 8.3 was observed. This independent titration experiment leaves very little doubt that C161 is responsible

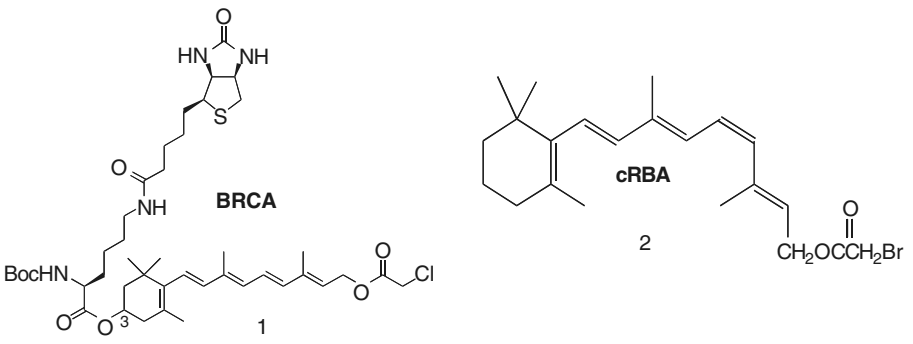

Fig. 6 Retinoid affinity-labeling agents.

for the ascending limb of the pH versus rate profile for LRAT.

With respect to the higher pKa ~10, this could be either due to an essential lysine or a tyrosine residue. These are the only amino acids with pKa's that reasonably could be ascribed to approximately 10. Site-specific mutagenic experiments on the relatively conserved lysine residues in LRAT (K90, K95, K104, K133, K134, K147, K180, and K186) (Fig. 5) were performed and showed that none of the lysine residues were essential for catalysis of tLRAT. Therefore, lysines can be eliminated as being responsible for the pKa ~10. The conserved tyrosine residues were also studied as candidates. Of these residues, tyrosine 154 is the most highly conserved of all of the tyrosine residues, as shown in Fig. 5. Indeed, of the relatively highly conserved tyrosine residues, only the Y154F mutation showed no activity. For comparison sake, the Y64F, Y118F, and the Y167F mutations were also studied, and all of those had substantial, if not full, activity. Therefore, we ascribe the higher pKa to tyrosine 154 and this suggests that LRAT operates via a catalytic triad in which C161, H60, and Y154 are essential for catalysis. Further inspection of Fig. 5 reveals that there is a bifurcation in the LRAT family. All of the LRAT family contains a cognate H60 and C161, but only a distinct subset contains a cognate of Y154. The enzymes that do not contain the Y154 are likely to be in the thiol protease wing of the LRAT superfamily. We, of course, have not done any mechanistic experiments on the protease family, and therefore do not know which other amino acids are essential for catalysis. A catalytic mechanism involving the catalytic C161, H60, and Ty154 in LRAT action is shown in Fig. 7.

3.2 Molecular Function of RPE65

The general role of RPE65 as a tRE chaperone is described in the Introduction section. The first indication of this was made by showing that a retinoid affinity-labeling agent (Fig. 6, compound 1) labeled RPE65. The all-*trans*-analogs (bromo and chloro esters) containing a biotin moiety attached to the 3-position of the retinoid were studied. The probes have two advantages over other biotinylated probes currently in use. A major advantage is the inclusion of a base cleavable moiety. Proteins labeled with these biotinylated derivatives are bound to tetrameric Avidin columns. Because the biotinylated moieties are adducted to the protein via base-sensitive ester linkages, we can wash the nonlabeled proteins from the Avidin matrix, and then simply raise the pH to 11 to cleave the esters and isolate the labeled protein with a carboxymethylene group adducted to an active-site residue. This makes our studies extremely straightforward in terms of the identification of labeled proteins. In addition, since base-sensitive linkages are imbedded in the probe, we are able to elute the proteins from high-affinity tetrameric Avidin columns with close to 100% yield. This labeling technology proved to be exceedingly useful in the discovery that RPE65 is a tRE-binding protein. Essentially, two proteins in RPE membranes were labeled. The minor protein is LRAT, which is expected since tRBA is known to label LRAT. Unexpected was the profound labeling of RPE65 by the retinoid reagent. RPE65 is labeled by the derivative in a time-dependent, and saturable fashion. The labeling was blocked by tRE, but not 11-*cis*-retinyl ester (cRE), oleyl alcohol or cROL, showing strong specificity in the binding reaction. Biochemical analysis

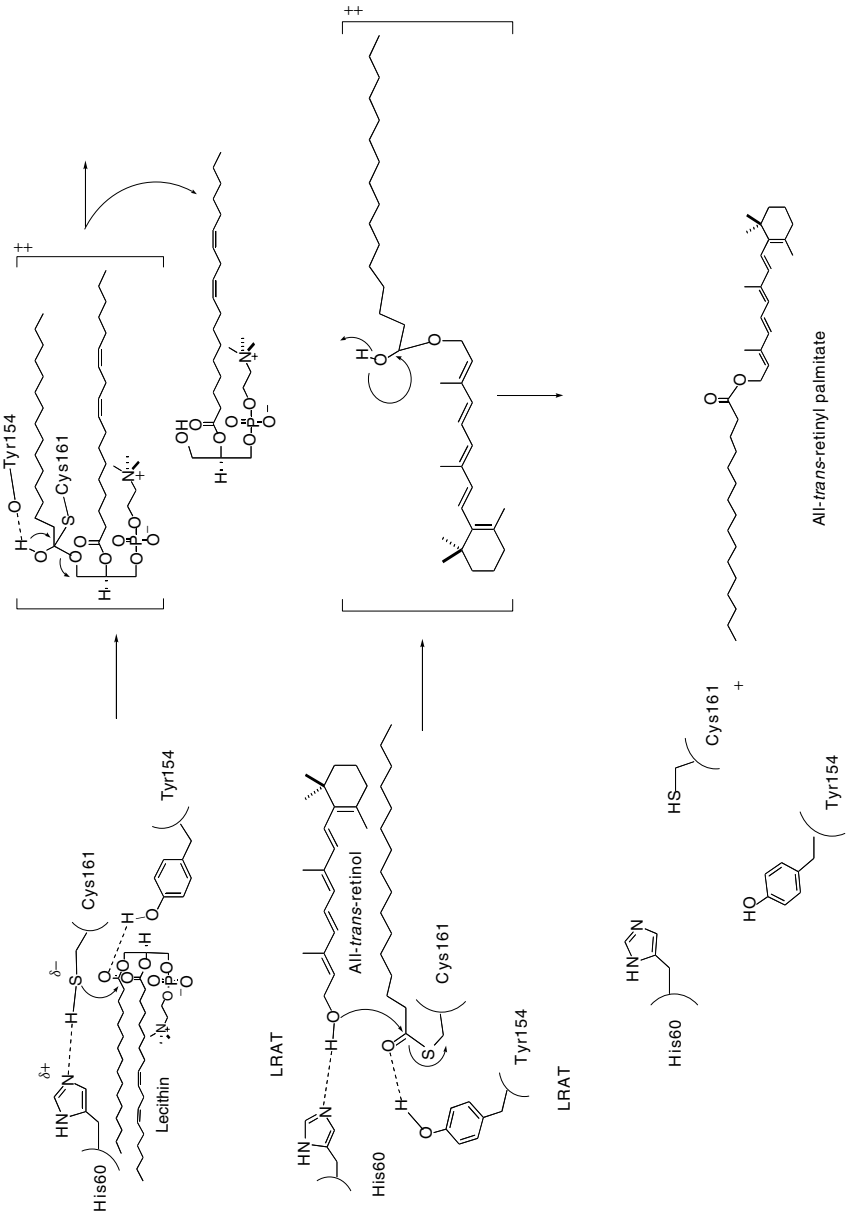

Fig. 7 LRAT mechanism showing the involvement of H60, Y154, and C161.

showed that two cysteine residues were labeled: C231 and C448. It is expected that these two sites may be involved in the active-site binding of tREs. These experiments were the first indication that RPE65 is a tRE-binding protein.

Following these labeling experiments, direct equilibrium fluorescence binding measurements were carried out, which showed that tREs bind in a saturable and specific fashion. We investigated the binding of all-*trans*- and 11-*cis*-retinyl esters, along with their congeneric alcohol derivatives, to freshly prepared, membrane-bound bovine RPE65 (mRPE65). Binding of tREs was of substantially higher affinity than for cREs and for tROL and cROL. The K_D for tRP is 47 nm. The binding constant for 11-*cis*-retinyl palmitate (cRP) is 2546 nM. The binding constant for tROL is 1463 nM and for cROL it is 2171 nM. We suggest that mRPE65 is a chaperone for highly hydrophobic tREs and mobilizes them as they enter the visual cycle for processing by IMH. The role of RPE65 in vision goes beyond its simple role as a tRE-binding protein.

Studies on mRPE65 suggest that it is part of the rate-limiting step(s) in the visual cycle. For example, mutations in RPE65 have been found which diminish rates of regeneration in WT mice and A2E formation in *Abcr* (*Abca4*) −/− mice (106). The mutational data are supported by small-molecule inhibitor data from our laboratory on retinoic acid. Accutane, 13-*cis*-retinoic acid, is a drug known to be effective in the treatment of certain dermatological diseases, including acne. Since night blindness is a major side effect of Accutane, we wondered whether the retinoic acids might specifically bind to mRPE65 and inhibit its function. Using fluorescence methods, we showed that tRP specifically binds to mRPE65. Accutane (13-*cis*-retinoic acid) also binds to mRPE65 with a $K_D = 195$ nm, while all-*trans*-retinoic acid specifically binds with a $K_D = 109$ nm. This is to be compared with the binding of tRP with a K_D of 47 nm. Since 13-*cis*-retinoic acid and all-*trans*-retinoic acid are equilibrated *in vivo*, the binding of both retinoic acids to mRPE65 is of interest. We went on to further study the interactions of the retinoic acids on tRE processing in the visual cycle and found that the competition of retinoic acid with tREs was evidenced by a diminution of the formation of cROL in the *in vitro* system. These studies demonstrate that the retinoic acids are competitive with tRP, both in direct competition assays, and they also compete with tRP visual cycle function. Thus, we suggest that at least one target for the retinoic acids is mRPE65. It had previously been shown that Accutane inhibits cROL dehydrogenase, but this inhibition does not account for the effect of Accutane on overall inhibition biosynthesis of 11-*cis*-retinoid biosynthesis in the visual cycle. We believe that this inhibition of RPE65 by the retinoic acids explains limiting of 11-*cis*-retinoid biosynthesis by these drugs. In addition, these experiments provide evidence for the rate-limiting nature of RPE65 function in the visual cycle.

The central role of RPE65 in visual cycle performance is further underscored by its likely importance in the regulation of retinoid fluxes through the cycle. Earlier we demonstrated one element of regulation of the visual cycle, namely, the apparent feed back inhibition of IMH by cROL. Chemical biological studies on RPE65 have uncovered an additional mode of regulation. There are two functionally distinct forms of RPE65, one membrane bound (mRPE65) and one soluble

(sRPE65). We found that mRPE65 is at least triply palmitoylated and sRPE65 is largely unpalmitoylated. Palmitoylation of RPE65 occurs at C231, C329, and C330. This palmitoylation explains the membrane association of mRPE65. We had already shown that mRPE65 binds to tRP with a $K_D = 47$ nM and to tROL with a $K_D = 1463$ nM. In the present study, we found that sRPE65 binds tROL with a $K_D = 65$ nM and tRP with a $K_D = 1235$ nM. In other words, mRPE65 and sRPE65 show opposite binding specificities. Most interestingly, LRAT uses mRPE65 as an acyl donor and acylates tROL to tRP. The kinetics of palmitoyl transfer to tROL with mRPE65 is sigmoidal, suggesting a regulatory role for this process. Overall, mRPE65 acts as a peptidomimetic of lecithin. In the process of forming tRP, mRE65 is functionally converted into sRPE as the product shows retinoid-binding behavior identical to sRPE65. It was also found that sRPE65 acts as a RBP and facilitates the esterification of tROL by LRAT. Furthermore, in the presence of mRPE65, cROL becomes an excellent substrate for LRAT in the formation of cRP. This suggests that the previously described feed back inhibition of IMH by cROL is at least partly due to the conversion of mRPE65 → sRPE65. This is directly revealed by studying the processing of ^{3}H-cROL biosynthesis in RPE membranes pre-incubated with cold cROL. The cold cROL is photochemically destroyed before incubation with ^{3}H-tROL. Here, a pronounced lag is observed, suggesting that the sRPE65 → mRPE65 reaction is partly rate limiting.

Overall, these experiments reveal a new role for LRAT, which acts as a molecular switch. mRPE65 is a palmitoyl donor, revealing a new acyl carrier protein role for palmitoylated proteins. When chromophore synthesis is not required, mRPE65 is converted into sRPE65 by LRAT, and further chromophore synthesis is blocked. These studies reveal new roles for palmitoylated proteins as molecular switches and LRAT as a palmitoyl transferase whose role is to catalyze the mRPE65 → sRPE65 conversion (Fig. 8).

3.3 The Isomerization Reaction

3.3.1 tREs as IMH Substrates in Rod- and Cone-dominated Species

As described earlier, an IMH mechanism is central to the operation of the visual cycle. In this mechanism, tREs are the substrates for isomerization and cROL is the product. The initial experiments in support of an IMH route relied on the use of tRBA, a selective LRAT inactivator. Inactivation of LRAT with tRBA produces an *in vitro* phenotype in which tREs are not formed from tROL, and hence isomerization cannot proceed. Similar experiments with additional inactivators produce the same result. The LRAT knockout mouse provides an *in vivo* cognate of these experiments, and, indeed, 11-*cis*-retinoids are not synthesized here either. However, it has been suggested that a tROL isomerase route may provide an alternative pathway to cROL biosynthesis. To assess whether such a pathway is quantitatively significant, a version of a pulse-chase experiment was performed.

The central problem in addressing whether the isomerization substitute is tROL or tRE is dealing with the rapid interconversion of the two putative substrates, as compared to the rate of isomerization. Thus, rapid interconversion makes

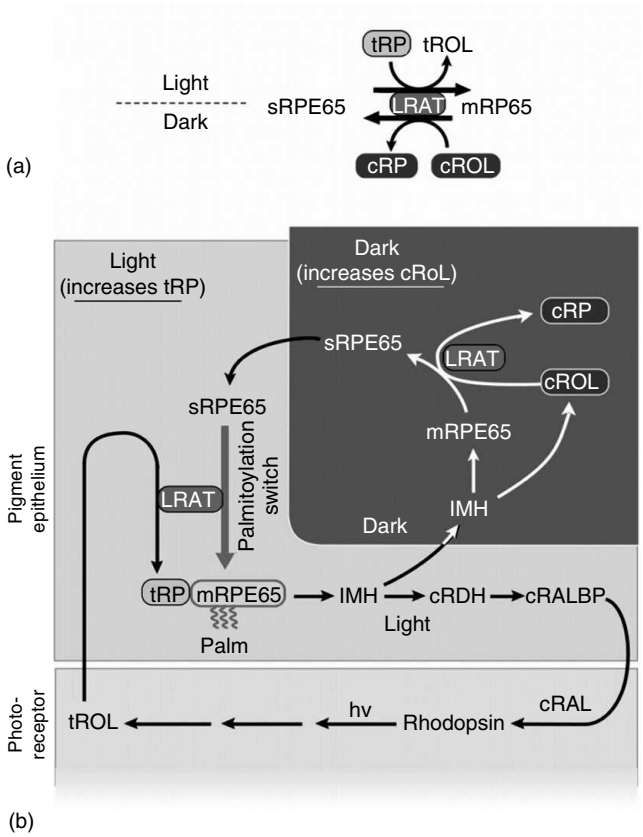

Fig. 8 Flow of retinoids in the visual cycle. (a) How the palmitoyl switch would behave in light and dark. (b) The flux of retinoids in the visual cycle and the role of the palmitoyl switch in directing their flow.

it impossible to carry out a standard pulse-chase experiment with either tROL or tRE because the pools will interconvert prior to isomerization. However, a pulse-chase experiment can be performed if the interconversion of tRE and tROL is blocked. This is readily done using tRBA to inhibit tRE synthesis and ebalactone A/B to inhibit tRE hydrolysis. Under these conditions, we can start with either high specific activity (^{3}H)-tRE/cold tROL or high specific activity (^{3}H)-tROL/cold tRE. The isomerization reaction is initiated and the specific activity of the isomerization product cROL is measured. The result could not have been more clear-cut. When the tRE pool is radioactively labeled, the resulting cROL is labeled with the same specific activity as the precursor tRE. The converse is true with tROL. These data unambiguously establish tRE as the substrate for isomerization.

Using this pulse-chase technique along with other approaches, we explored the mechanism of regeneration in a cone-dominated animal (chick). There

are known differences in the cone regeneration process compared to rod regeneration. For one thing, 11-*cis*-retinoid regeneration can occur in cone Müeller cells, although the quantitative importance of processing here as compared to flux through the RPE is unknown. Within experimental error, 11-*cis*-retinoid regeneration in rod-dominated animals is confined to the RPE. Secondly, tRE synthesis in cone-dominated species is stimulated by palmitoyl CoA, suggesting an atypical LRAT-type mechanism, or a novel tRE synthetase activity altogether. Given these observed differences, we explored the nature of the isomerization substrate and found it to be tRE, just as in rod-dominated species. The cone regeneration pathway was established using three complimentary approaches. First, no isomerization occurred after preincubation of chick RPE/retina with tRBA, which blocks LRAT, followed by addition of tROL that prevented isomerization. This is consistent with tRE being the isomerization substrate. Secondly, pulse-chase experiments, along the lines discussed above, showed that only tRE is processed into cROL. Finally, 11-*cis*-retinyl bromoacetate (cRBA), a specific affinity-labeling agent for IMH (Fig. 6, compound 2), blocked the processing of tRE into cROL. These data leave little doubt that cone and rod regeneration share the same overall molecular logic. An interesting additional issue here, though, is the nature of the RE synthetase. Western blotting, with anti-LRAT antibody shows a 21-kDa protein, as does labeling with BRCA. The standard LRAT molecular weight is approximately 25 kDa. Furthermore, chick RE synthase is also inactivated with tRBA, an affinity-labeling agent of LRAT. These data suggest an LRAT-type mechanism. However, RE synthesis in chick is stimulated by palmitoyl CoA (Palm CoA), but not by dipalmitoyl phosphatidyl choline (DPPC), an acyl donor for LRAT.

3.3.2 A Specific Inactivator of IMH and an Approach to IMH Identification

The identification and cloning of LRAT was made possible by the specific affinity-labeling agents tRBA and biotinylated derivatives thereof. IMH also presents a difficult problem with respect to identification owing to its lability in detergent and miniscule amount. Hence, a specific affinity-labeling agent directed at IMH was sought. Because IMH is strongly inhibited by 11-*cis*-retinoids, we prepared the 11-*cis*-retinoid-based affinity-labeling agent 11-*cis*-retinyl bromoacetate (cRBA) (Fig. 6, compound 2).

cRBA was designed as an affinity-labeling agent for IMH by analogy to the reagent used (tRBA) for the identification of LRAT. This molecule (cRBA) is a relatively high-affinity ($K_i = 0.1\ \mu M$) and a pseudo first-order inactivator ($kinh = 1.9 \times 10^{-3}\ s^{-1}$) of IMH action. The molecule shows saturable kinetics and a pseudo first-order mode of inactivation. This demonstrates a highly specific mode of inactivation of IMH action. Preliminary data on the use of ^{3}H-cRBA reveals the labeling of proteins largely in the 45- and 35-kDa region, and in the approximately 200-kDa region. We believe that the latter labeling occurs because IMH is likely to be found in a multienzyme complex whose interactions may partly survive SDS gel electrophoresis.

As mentioned earlier, IMH action can occur in one or two steps. As long as ester hydrolysis occurs subsequent to isomerization, the same thermodynamic imperative is met. The first step could involve *trans* → *cis* isomerization at the ester stage, and then the second step would involve specific hydrolysis of the

cRE. cRE hydrolase can be assayed in RPE membranes, and we were able to show that cRBA had no effect on general cRE hydrolase activity. So, if there should be a two-step reaction (isomerase/hydrolase) and the commonly assayed RPE cRE hydrolase activity is relevant in the visual cycle, then we know that cRBA is likely to be directed at the isomerase. The discovery of cRBA as a powerful and specific inactivator of IMH may be important in the identification and cloning of this protein.

Direct purification approaches to the identification and cloning of isomerohydrolase have not proved fruitful over the years, suggesting that alternative approaches will be required. One approach, of course, involves cloning by analogy. However, since the IMH reaction is a relatively unique reaction, this approach may be difficult to implement. Indirect approaches, such as the affinity-labeling approach described above, may provide an alternative approach to the identification of IMH. In this functional proteomic approach, IMH is specifically labeled with specific affinity-labeling reagents, such as cRBA, in mixtures of proteins and the labeled protein(s) is harvested for sequence analysis. Cloning and expression of the protein is then used to determine whether the correct protein has been identified. This approach was successful in the identification and cloning of LRAT and is being applied to the identification of IMH.

4 Possible Medical Significance of Studies on Retinoid Processing in the Visual System

Every time the visual cycle is traversed a molecule of rhodopsin is bleached and a molecule of all-*trans*-retinal (tRAL) is generated (Fig. 1). Like other aldehydes, tRAL is chemically reactive and needs to be detoxified enzymatically by reduction to form vitamin A. The tRAL that is generated can partition productively and re-enter the visual cycle, or it can chemically react with biological amines to generate retinotoxic products (Fig. 9). In these reactions, a tRAL forms a Schiff base with the amine followed by enamine formation and then a series of reactions that generate the toxic compounds irreversibly. These reactions are similar in kind to those found in diabetes, where excess glucose aldehyde chemically reacts with proteins by reversible Schiff base formation followed by further chemical reactions, which irreversibly secures the glucose moiety to the protein. These chemical reactions are thought to be of primary importance in the etiology of diabetes.

In the case of tRAL reactions, the salient biological amine in question is photoreceptor phosphatidyl ethanolamine, which reacts with tRAL to generate the toxic lipofuscins of RPE cells (Fig. 9). The best-characterized RPE lipofuscin fluorophores is the diretinal conjugate A2E, its photoisomer iso-A2E, and other minor *cis*-isomers of A2E. These fluorophores are generated from sequential reactions between all-*trans*-retinal and phosphatidylethanolamine (2 : 1). The A2E family perturbs cell membranes, confers susceptibility to blue light-induced apoptosis and alters lysosomal function. In light of this adverse behavior, there is considerable interest in retarding A2E formation as a means to prevent vision loss in retinal degenerative diseases including Stargardt's disease and perhaps age-related macular degeneration. In Stargardt's disease, a juvenile form of macular degeneration, excessive accumulation of A2E occurs because of the presence of

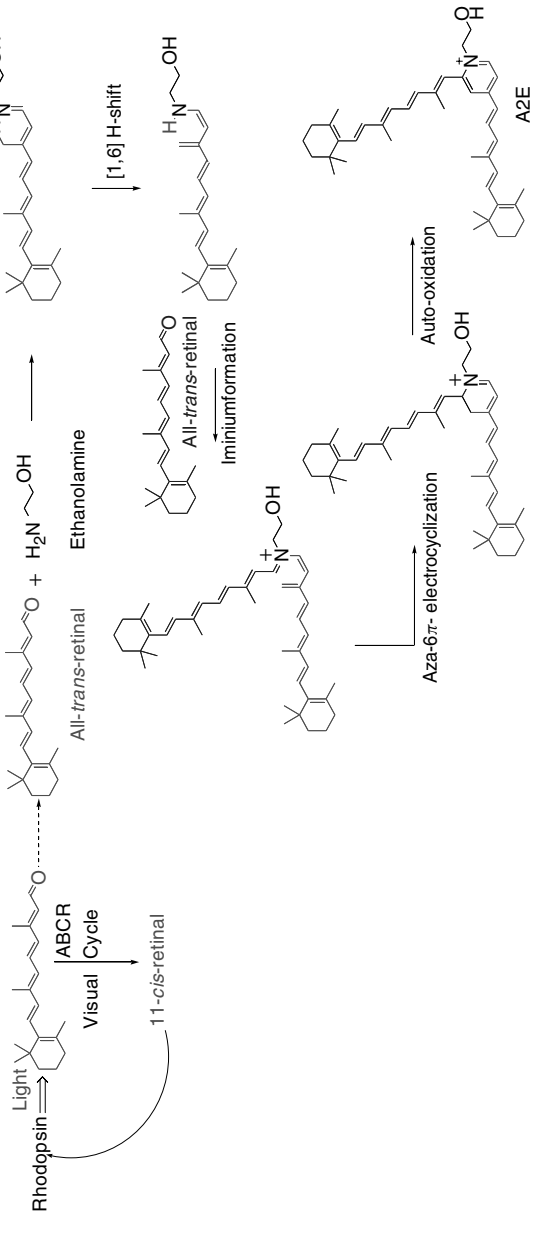

Fig. 9 All-*trans*-retinal partitioning between the visual cycle and A2E formation.

inactivating mutations in a pump that removes precursors to A2E before they proceed to form A2E and conjugates. Because accumulation of A2E, either through age-related processes or because of mutations, as in Stargardt's disease, it has become increasingly clear that small-molecule inhibitors, which limit the visual cycle, and thus limit the formation of A2E, may be of therapeutic value in the treatment of visual disorders. By limiting fluxes through the visual cycle by inhibiting key enzymes and retinoid-binding proteins thereby reducing all-*trans*-retinal formation, it should be possible to decrease formation of A2E. Inhibiting the visual cycle would probably only affect scotopic vision (night blindness) in a marginal way, but would not affect cone vision because the cones preferentially take up 11-*cis*-retinoids. Moreover, even though rods account for >95% of total photoreceptors, rod function is not very important for most people in industrial societies as a consequence of the advent of artificial light.

To effectively inhibit the visual cycle, a target must be chosen, which is at least partly rate limiting. RPE65, described above, may be such a target. At least one mutation in RPE65 is known to inhibit retinoid flux through the visual cycle, while also inhibiting A2E accumulation. Moreover, a drug, known to cause night blindness in humans and A2E accumulation in mice, interferes with RPE65 function. This again suggests that RPE65 is part of the rate-limiting step. The drug in question, Accutane™ (13-*cis*-retinoic acid), which is used to treat serious dermatological disorders, binds powerfully to mRPE65 and displaces all-*trans*-retinyl esters, making the latter unavailable for processing by IMH. While it is highly unlikely that the highly toxic retinoic acids are serious candidates for prophylactic treatment of macular degeneration, the studies suggest the realistic possibility that appropriate nontoxic small-molecule antagonists can be found to limit the visual cycle and treat retinal degenerative diseases.

Keywords

Attachment Sites (att)
The sequences located at the viral DNA ends that are necessary and sufficient for IN binding and full-site integration activity.

Full-site Integration
The IN-mediated concerted insertion of two viral DNA ends into cellular DNA *in vivo* or into an exogenously provided DNA target *in vitro*.

Human Gene Therapy
The retrovirally mediated transduction of a therapeutic gene into the human chromosome.

Human Immunodeficiency Virus
Human retrovirus that is the causative agent of HIV-1/AIDS.

Integrase (IN)
The viral enzyme that possesses 3′ OH nuclease and strand transfer activities, both of which are essential for proper insertion of the retrovirus DNA genome into host DNA.

Mobile DNA Elements
Small DNA elements similar to retroviral DNA in structure that serve to provide self-mobility within and between cells. Retrotransposons contain a DNA structure that is similar to retroviral DNA. Many other mobile DNA elements dissimilar to retroviruses also exist in nature.

Preintegration Complexes (PIC)
Cytoplasmic viral DNA-protein complexes formed after reverse transcription of the viral RNA genome. PIC are transported into the cell nucleus allowing integration of the viral DNA genome into host chromosomes.

Provirus
The term used to describe the integrated viral DNA genome in cell DNA.

Retrovirus
Retroviruses comprise a large family of viruses that contain RNA as their genome. In a retrovirus, a cell-derived membrane envelope encases the genomic RNA along with viral enzymes and structural proteins. The replication cycle requires reverse transcription of the RNA genome into DNA followed by integration of this DNA by viral integrase into host chromosomes.

Synaptic Complex
The assembly of IN together with the linear viral DNA genome; a nucleoprotein complex capable of mediating full-site integration.

Retroviruses are unique in nature in that they require the integration of their viral DNA genome into host chromosomes for replication. This article summarizes and compares the integration machineries of three retroviruses that have increased our understanding of HIV-1/AIDS and the possibility of developing a safe retrovirus vector for human gene therapy. HIV-1, a retrovirus, is a significant pathogen for humans. After virus entry into the cell, reverse transcription of the retroviral RNA into DNA allows the formation of cytoplasmic preintegration complexes (PIC) that are subsequently transported into the nucleus. Though the pathway of infection is similar, the biological machineries required for nuclear transport of PIC are significantly different between HIV-1, murine leukemia, and avian retroviruses. These transport mechanism variances have aided the development of retrovirus vectors for delivery of genes into nonproliferating cells. The viral integrase (IN) within the PIC integrates the viral DNA into host chromosomes. The consequences of viral DNA integration are multifaceted. Sequencing of the human genome and viral DNA integration sites in the genome has shown that integration by HIV-1 favors actively transcribing genes. Murine leukemia virus prefers to integrate into or near transcription start sites while avian retrovirus shows no significant bias for transcription start sites and only a weak preference for active genes. The two- to threefold site selection preferences suggest that cellular proteins may influence the PIC to integrate into some host target sites. However, all three retroviruses can integrate their DNA into many different sites in all of the chromosomes. Reconstitution of synaptic complexes using purified IN and viral DNA substrates, possessing similar integration capabilities as PIC, has provided and will provide further molecular insights into the PIC. Understanding the biochemical machineries within PIC contributes valuable information for developing inhibitors to the HIV-1 IN. In particular, combinational drug therapy against different HIV-1 enzymatic targets have been successful at the clinical level and these therapies should be enhanced by the addition of IN inhibitors.

1
Retrovirus Replication and Integration Overview

1.1
Replication Pathway

Retroviruses are animal viruses ubiquitously present in nature. They comprise a large group of viruses that share a common mode of replication. Retroviruses attach to a specific receptor(s) on the cell membrane prior to entry into the cell (Fig. 1). After fusion and penetration of the virus into the cell, the viral single-stranded RNA genome located in the virion core undergoes reverse transcription yielding a double-stranded DNA copy of the viral genome. The viral DNA genome contained in the PIC (preintegration complexes) is transported into the nucleus and undergoes IN-mediated integration into the cellular genome. The integrated viral DNA genome is transcribed by cellular RNA polymerase II into messenger RNA that codes for viral proteins and also serves as virion genomic RNA. The virion RNA

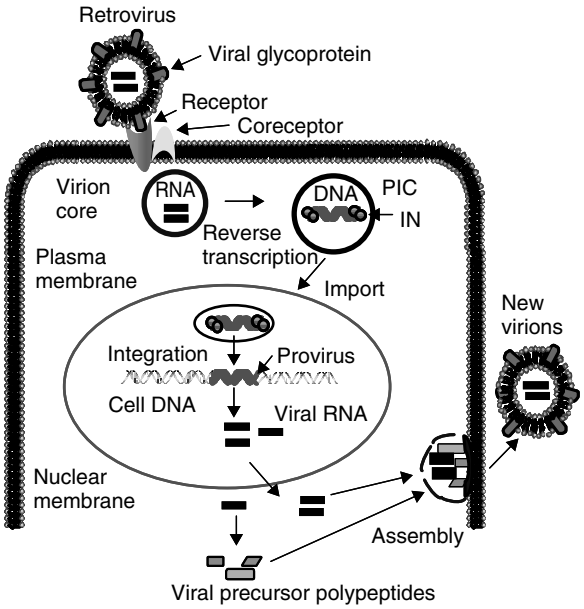

Fig. 1 Retrovirus replication cycle. The viral envelope glycoproteins (red structures) on retroviral particles attach to a specific receptor (multiple colors) on the cell surface leading to fusion and entry of the virion core into the cytoplasm. Sometimes viruses, like HIV-1, use a coreceptor (yellow) for fusion and entry into the cell. The viral RNA (two identical copies) in the virion core is reverse transcribed into double-stranded DNA. PIC are formed in the cytoplasm. IN (dimer, green circles) is located at the ends of the viral DNA in the PIC. These nucleoprotein complexes are transported into the nucleus by one of several different mechanisms depending on the particular retrovirus. The viral DNA is integrated by IN into the cell DNA, which is subsequently transcribed into viral RNA. The full-length viral RNA and spliced messenger RNAs are transported into the cytoplasm for protein translation. Viral proteins along with full-length RNA are assembled together as immature virus particles at the plasma membrane prior to release of new infectious virions. (See color plate p. xxxvii.)

is transported along with viral precursor polypeptides and cellular proteins to the cell membrane where immature, noninfectious virus particles are formed. The immature virus particles incorporate the plasma membrane from the cell as part of its membrane structure. During release of the immature particles, the viral protease processes the viral precursor polypeptides allowing the production of new infectious virus particles. These virions infect adjacent cells and the replication cycle is repeated. HIV-1, the infectious human retrovirus that causes AIDS, follows the earlier-mentioned pathway. Variations of the replication pathway exist within the large family of retroviruses, but all include reverse transcription of the RNA and

integration of the viral DNA genome into cellular DNA.

1.2 Consequences of Integration

Following integration of the viral DNA genome into the host chromosomes, the parasitic retrovirus utilizes host-cell machinery to self-replicate. In model systems, some proviruses do not adversely affect cellular genes because either the viral DNA integrates into nonessential regions of the chromosomes or because cellular mechanisms silence the provirus. In addition to being responsible for the production of new virus particles, the integrated provirus can exert multiple effects onto the infected cell. The integration process is essentially irreversible, although on occasion, host-cell mediated homologous recombination between the ends of the integrated DNA eliminates most or all of the viral internal genes. The remaining viral regulatory signals in the cell DNA can influence the transcription of cellular genes just as they do with the intact provirus.

Proviruses can produce mutations in cellular genes that affect the growth properties of the cell. Mutations in these genes result in either overproduction or alterations of normal growth control proteins modifying the replication properties of cells in culture. These abnormal cells can cause cancers when introduced into animal model systems. In some cases, integration of the viral DNA allows the simultaneous transcription of viral and cellular genes together into one messenger RNA that is subsequently packaged into virion particles. This ''capturing'' of cellular growth regulatory genes into infectious virions results in the transduction of cellular genes from infected cells to normal cells. Further discussion of the consequences resulting from viral DNA integration into various regions of the human chromosome will be presented later.

In summary, studying the genetic consequences of retroviral DNA integration into the host chromosomes of cells and the use of various animal model systems has enabled scientists to further their pursuit to understand human cancers. The initial discovery of the ''capture'' of regulatory cellular genes by retroviruses has prompted scientists to identify many cellular regulatory genes.

2 Retrovirus Preintegration Complexes

2.1 Physical and Molecular Properties

The virus particle is fused with the plasma membrane and it enters the cytoplasm of the cell (Fig. 1). During and following reverse transcription, the viral IN (integrase) associates with viral DNA to form a cytoplasmic nucleoprotein complex termed PIC (Fig. 1). They can be purified from the cytoplasm of virus-infected cells. The PIC are physically large having a sedimentation velocity of ~80 to 120 S. Within the PIC, IN first removes two nucleotides from the 3′ OH blunt-ended termini of the linear DNA genome. IN forms a stable association with the 3′ OH recessed ends of the viral DNA. PIC are then transported into the nucleus and IN inserts the two 3′ OH recessed DNA ends in a concerted fashion into the host genome (Figs. 2 and 3). A successful insertion of both viral DNA ends into the host DNA is termed *full-site integration*. This event can be mimicked *in vitro* by introducing purified PIC to an exogenously supplied DNA

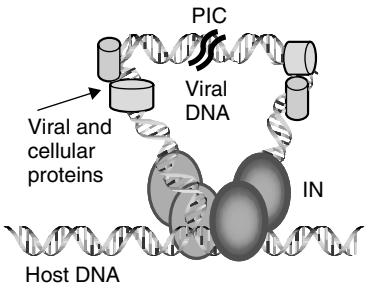

Fig. 2 Pictorial representation of how IN holds the two viral DNA ends together within PIC at the time of integration into the host genome. The entire linear viral DNA (10 kbp) is not drawn to scale as indicated by the dark lines in the viral DNA. The ends of the DNA are inserted by IN (illustrated as dimers) into the host or target DNA. IN recognizes specific *att* site sequences at the viral 3′ OH recessed DNA ends (Fig. 5). To produce the appropriate host-site duplications upon integration into the target DNA, the distances between the 3′ OH ends held together by IN in PIC must be in the ~16 to 20 Å range (Fig. 3). The number of IN subunits required at the ends of the viral DNA for full-site integration is unknown. A tetramer is shown for illustration purposes only. The three separate domains on these simple models of IN are also not drawn. Several cellular and viral proteins associated with the PIC are represented as gray and light blue objects. This model displays the viral DNA ends in a parallel fashion although the ends could also exist in an antiparallel fashion. (See color plate p. xxviii.)

target (Fig. 2). Molecular analysis shows that the 3′ OH ends act as nucleophiles that form a covalent linkage between the viral ends and the 5′ ends of the target DNA at staggered sites of insertion. The host-site DNA gaps and the 5′ two base-pair viral DNA that overhang at the viral-host junctions undergo repair by cellular enzymes, producing an integrated provirus (Fig. 3). The small size host duplications created at the integration site range from 4 to 6 bp and is therefore a function of the specific retrovirus IN (Fig. 3).

The mode of transport of cytoplasmic PIC across the nuclear membrane is different among retroviruses and thus affects their ability to integrate their DNA in either dividing or nondividing cells (Fig. 1). In addition to reverse transcriptase, IN, and the viral DNA genome, PIC contains several viral proteins. IN and these proteins, along with one or more cellular proteins (Fig. 2), appear to orchestrate the transport of PIC into the nucleus. HIV-1 and avian retroviruses have active transport mechanism(s) because they integrate their DNA in both nondividing and dividing mammalian cells. Avian retroviruses integrate their DNA less efficiently in nondividing mammalian cells suggesting a less efficient transport mechanism than HIV-1. Murine leukemia viruses can only efficiently transport their PIC in dividing cells when the nuclear membrane breaks down during cell division (passive transport).

In summary, the efficiency with which the earlier-mentioned three viruses infect nondividing cells correlates with their respective transport mechanisms across the nuclear membrane. Understanding the basis for these restrictions is of particular importance in the development of retroviral vectors for human gene therapy.

Retroviral vectors containing only the essential elements required for reverse transcription and integration can be constructed *in vitro*. These vectors have the same integration properties of normal retroviruses implying that they produce structurally analogous PIC. Most vectors (replication-defective) obtain their viral proteins needed for the initial transduction of cells from a retroviral packaging cell in trans, thus preventing additional rounds of infection. Some vectors have self-inactivating features that eliminate unwanted transcription from cellular genes. Pseudotyping vectors with either specific or nonspecific viral glycoproteins (Fig. 1)

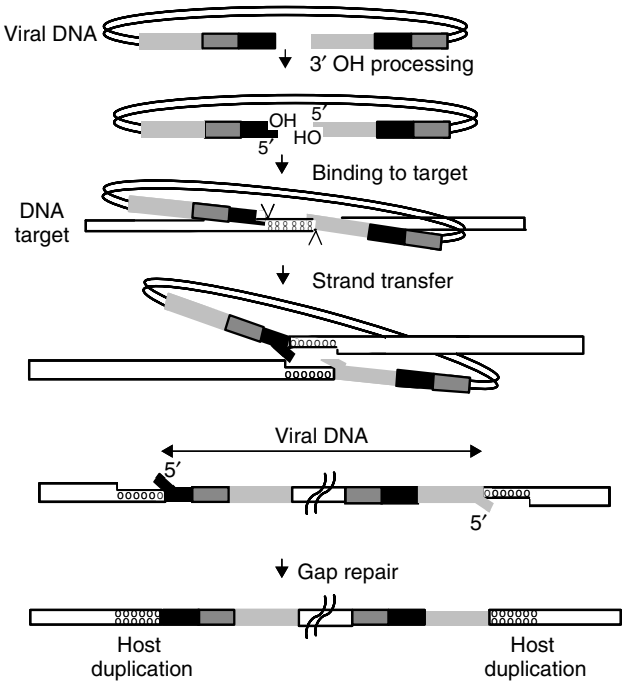

Fig. 3 Steps necessary for integration of the linear viral DNA genome into the host chromosome. The 10-kbp linear blunt-ended viral DNA is represented at the top. The different shaped areas on the viral DNA represent different viral regulatory regions including the terminal attachment sites for IN recognition. IN cleaves two nucleotides from the 3′ OH termini prior to binding to the target DNA. The target DNA represents either the host genome or exogenously added target. IN inserts the 3′ OH recessed ends into the target DNA at stagger sites upon integration. Host repair enzymes remove the 5′ 2-bp overhang on the viral DNA and fill in the gap between the host and viral DNAs. For avian retrovirus IN, the stagger sites are 6 bp apart on opposite strands of the target. The host-site duplications for avian, HIV-1, and murine leukemia retroviruses are 6, 5, and 4 bp, respectively. (Adapted from Brown, in: Coffin, J.M., Hughes, S.H., Varmus, H.E. (1997) *Retroviruses*, Cold Spring Harbor Laboratory Press, Cold Spring Harbor, New York.)

can bestow on these vectors the ability to infect a variety of mammalian cells including human cells. Integration of a gene of interest carried by a retrovirus vector into nondividing or quiescent human cells would have a significant advantage over a vector requiring rapidly replicating cells. For instance, HIV-1 vectors can transduce differentiated neurons, quiescent hematopoietic stem cells, and macrophages in contrast to murine leukemia virus–based vectors, which require dividing cells.

In summary, the different integration machineries of retroviruses have an influence in which cells of a specific retrovirus

can efficiently replicate via integration of their DNA. Hopefully, further progress in the development of safe retrovirus vectors will allow treatment of certain genetic defects in humans.

2.2 Host Chromosomes Target Site Selection *In Vivo*

Understanding how retroviruses preferentially infect either dividing or nondividing cells is critical for selecting a particular retrovirus vector that is best suited for a specific protocol or experimental approach. Is it possible to direct the insertion of a gene of interest by a retrovirus vector into a specific region of the human chromosome? Sequencing of the human genome has provided a platform through which it is determined whether retroviruses integrate their DNA genomes into distinctive chromosomal regions as observed in yeast retrotransposons. These retrotransposons like retroviruses have reverse transcriptase and IN enzymes and therefore employ similar modes of replication. Recent findings demonstrate that avian retroviruses and murine leukemia viruses as well as HIV-1 do indeed integrate their DNA preferentially into distinct regions of the human chromosomes. HIV-1 favors actively transcribing genes, murine leukemia virus into or near transcription start sites, and avian retroviruses show no significant preference for transcription start sites but only a weak preference for active genes. However, proviruses exist in all of the human chromosomes in various regions even though these retroviruses have integration site preferences (~two to threefold) for certain regions. Therefore, it is currently not possible to construct a retrovirus vector that directs integration of a gene of interest specifically into a desired chromosomal site.

The details of retroviral integration selectivity remain obscure. For some yeast retrotransposons, tethering their PIC complexes to specific transcription factors directs the integration machinery to a specific transcription site in the yeast chromosome. Several cellular proteins interact with HIV-1 IN in the PIC. Although some of these have been identified, there is little genetic proof that one or more of these proteins participate in or mediate integration selectivity. The macroscale pattern (chromosomal location) consisting of the net distribution of integrated provirus arises from the microscale (DNA sequence level) selecting of IN-mediated integration. This microscale selectivity is likely due, at least in part, to assistance from cellular proteins. *In vitro* target site selectivity data suggests that purified IN may favor certain physical DNA structures and possibly sequences for integration. Analyses of hundreds of viral DNA integration sites at the sequence level will be necessary to provide a more accurate assessment of which mechanism(s) may direct the selectivity and specificity of the PIC. Finally, integration selectivity may have cell (like nondividing cells) and tissue type specific requirements, which may be discovered by further analysis of viral DNA integration sites.

2.3 Integration Properties of Isolated PIC *In Vitro*

Isolation and purification of cytoplasmic PIC from murine leukemia virus-infected cells first provided an idealized model through which to understand the biochemistry of retrovirus integration. Again, IN within purified PIC catalyzes the insertion

of the two viral DNA ends in a concerted fashion into an exogenously supplied target with high efficiency and fidelity (Figs. 2 and 3). Other genetic and biochemical studies of PIC have enhanced our appreciation of the complex structural and functional nature of the PIC. For example, PIC captures a variety of cellular proteins that appear to allow the PIC to traverse the cytoplasm and to be imported into the nucleus. Further studies of the PIC are also necessary for elucidating the roles of IN and these cellular proteins in selecting DNA sites for integration into the host chromosomes. For instance, recent studies demonstrate that when purified HIV-1 PIC select host target sites *in vitro* (Figs. 2 and 3), the ~two to threefold preference for active transcribing genes selectivity observed *in vivo* is not evident. The results suggest that the cellular environment and the unique interactions of the PIC with cellular proteins may be critical for integration selectivity.

3
Synaptic Complexes Capable of Full-site Integration

3.1
Reconstitution of Synaptic Complexes with IN and Viral DNA Substrates Capable of Efficient Full-site Integration

It is difficult to obtain sufficient quantities of PIC from virus-infected cells to manipulate at the molecular and biochemical levels. The reconstitution of synaptic complexes possessing properties associated with PIC requires purified IN, viral DNA substrates, and possibly other viral and cellular proteins. It is easy to mimic the viral genome in size and sequence through the synthesis of model linear viral DNA substrates using recombinant DNA technologies. Isolation of purified IN from virions has only been accomplished with avian myeloblastosis virus. Recombinant HIV-1, murine leukemia virus, and Rous sarcoma virus (RSV) IN have been expressed in bacteria and other expression systems. To date, only avian myeloblastosis virus and recombinant RSV IN have the capacity to efficiently assemble synaptic complexes holding the two viral DNA ends in close juxtaposition to catalyze full-site integration *in vitro* (Fig. 2). No other viral or cellular proteins are required with avian retrovirus IN for efficient full-site integration. The fidelity for producing the avian host-site duplications (6 bp) by purified IN (Fig. 3) is greater than 95% with the reconstituted synaptic complexes closely matching the fidelity observed *in vivo* with PIC.

Numerous laboratories using recombinant HIV-1, murine leukemia virus, and other retrovirus species IN have demonstrated that these recombinant IN essentially lack the ability to efficiently assemble synaptic complexes (Fig. 2) capable of full-site integration. Numerous nonspecific integration reactions occur whereby IN either inserts the viral DNA substrates into other viral DNA substrates (autointegration) or inserts only one end into the added target DNA (half-site integration). It appears that recombinant IN is for the most part defective in forming the necessary protein–protein interactions required to form a stable synaptic complex *in vitro*. The possibility exists that other cellular proteins are required for HIV-1 IN to form stable synaptic complexes *in vitro* (Fig. 2). Biochemical studies with isolated PIC from HIV-1 and murine leukemia virus highly suggested that LEDGF/75, a transcription activator, and BAF (autointegration barrier protein) are critical

components responsible for nuclear transport and stability of the PIC, respectively. Genetic evidence is necessary to firmly establish if these and other identified cellular proteins may have a role in the direct integration process of the three retroviruses described in this chapter.

In summary, the study of isolated PIC and reconstitution of synaptic complexes for studying full-site integration have limitations in comparison to the process *in vivo*. However, further molecular insights into retrovirus integration will also require study of these integration machineries at the biochemical level.

4
Retrovirus Integrase

4.1
Origin and Structure of IN

IN was first identified in virion core structures isolated from purified avian myeloblastosis virus as a homodimer of subunits having a molecular weight of 32 000 Da each (Figs. 1 and 4). In virus particles, IN is proteolytically processed by a viral protease from the carboxy-terminal domain of the precursor polypeptide for reverse transcriptase. HIV-1 IN is similar in size to avian IN, while murine leukemia IN has a molecular weight of 42 000 Da. Avian and HIV-1 IN contain three structural domains (Fig. 4). The N-terminal domain (~50 residues) contains a zinc binding region, promotes multimerization of IN, and is necessary for full-site integration. The central or catalytic domain (~200 residues) contains a highly conserved triad of amino acids comprising the conserved D,D(35)E motif, which is involved in aligning divalent metal ions for enzymatic activities. The catalytic domain binds to both, the very terminal viral *att* sequences (Fig. 5) and target DNA. The C-terminal domain (~35 residues) also binds to *att* site sequences (~7–10 nucleotides from the end) to DNA target sequences, as well as being involved in multimerization of IN subunits. The multiple modes of DNA binding to both viral *att* and target sequences by IN implies that multiple

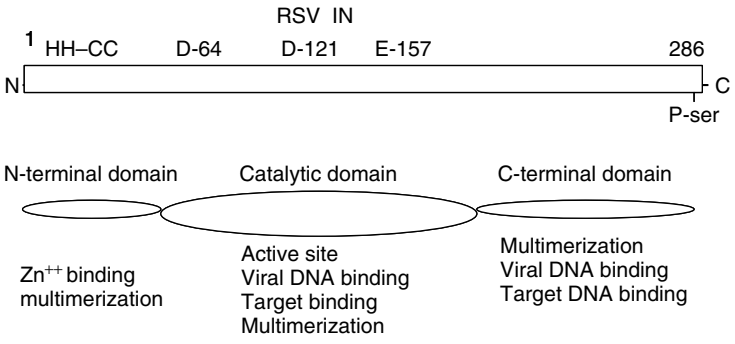

Fig. 4 Schematic representations of avian retrovirus IN. The Rous sarcoma virus (RSV) IN is 286 residues in length (top). The N- and C-termini are marked. The HH–CC (N-terminal domain), the conserved D,D(35)E motif (catalytic domain), and the C-terminal domain are indicated below the box. The functions associated with each domain are listed below. RSV IN is phosphorylated at Ser282. HIV-1 IN has a similar domain structure but is not posttranslationally modified.

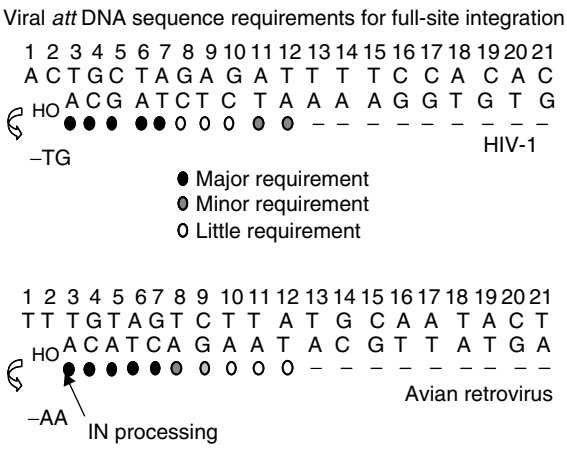

Fig. 5 Retrovirus *att* DNA sequence requirements for full-site integration. For simplicity, only one each of either the U5 or the U3 terminal sequences presence on linear viral DNA are shown. Both U3 and U5 *att* sites are necessary for full-site integration *in vivo*. HIV-1 U5 terminal sequences are shown on the top line. Below these sequences are circles indicating either a major, minor, or little requirement for IN enzymatic activities observed both *in vivo* and *in vitro*. The dash below each nucleotide indicates no requirement for IN activities. Murine leukemia virus terminal *att* sequences (not shown) are different than those shown for HIV-1. Similar requirements exist for murine sequences at these positions as shown for HIV-1 IN. The bottom line contains the U3 terminal sequences of avian retroviruses with the indicated requirement circles below each nucleotide. The arrow demonstrates IN cleaving two nucleotides from the blunt-ended viral DNA end. This cleavage occurs with all retrovirus IN.

subunits participate in full-site integration (Fig. 2).

The atomic structures of the three domains of IN have been determined individually or in two domain pairs. In solution as well as in crystal structures, the domains exhibit dimeric forms possessing huge surface areas for binding viral and target DNA, as well as for protein–protein interactions between the paired domains. Neither the structure of full-length IN nor IN bound to viral DNA *att* sites have been obtained.

4.2 Viral DNA–IN Synaptic Complexes

Investigators have exerted considerable effort to understand IN-viral DNA interactions in the hopes of designing drug molecules that inhibit HIV-1 IN. Investigations into the multidomain structures of IN (Fig. 4) provided molecular insights into IN activities, including 3′ OH processing, host target site selection, and strand transfer activities (full-site and half-site integration) (Fig. 3). For instance, IN cleaves specifically at the highly conserved CA dinucleotide in the viral *att* site (Fig. 5). IN exhibits no apparent binding preference for blunt-ended viral DNA ends over ends with other DNA sequences. Specificity appears to occur through conformational changes in IN that occur upon binding with the 3′ OH recessed ends. These conformational changes lock the complex into its proper ''strand transfer configuration,'' permitting subsequent catalysis (Fig. 5). For full-site integration, IN specifically holds the two *att* viral DNA ends in close juxtaposition (Fig. 2) requiring only the very terminal *att* sites as shown in Fig. 5. The point of joining in the target DNA by two active sites on different dimers of avian IN are known to be spaced 6 bp apart on opposite strands (Fig. 3), that is, ~18 Å for helical DNA. On the basis of *in vitro* experiments, several models have been proposed for IN–DNA complexes. Most of the models are composed of an IN tetramer (dimer of dimers) with two ends of viral DNA with only two

active sites out of four involved in full-site integration. An octamer of IN has also been proposed for holding together the viral DNA ends in the presence of target DNA. In summary, intensive investigation of the biochemical machinery has revealed the complex associations of IN with viral DNA *att* sites both within PIC and reconstituted synaptic complexes.

5 Human Gene Therapy

5.1 Success and Failure

HIV-1, murine leukemia, and avian retroviruses have preferences in selecting host sites for integration into host chromosomes. This preference by PIC to integrate viral DNA into different regions of the human chromosomes has added to our understanding of host-site selection, possibly permitting the insertion of genes of interest using retrovirus vectors. Considerable caution is necessary as illustrated by the use of murine leukemia virus as a vector for insertion of a gene to correct human X-linked severe combined immunodeficiency. Several years after gene therapy, two of the eleven successfully treated children developed T-cell leukemia because the vector inserted next to a human T-cell regulatory gene (*LMO2*), led to aberrant transcription and expression of the gene. These human cases of gene therapy–induced leukemia have long been understood to occur in animal model systems where different types of cancers have been induced by various retroviruses, called *insertional mutagenesis*. Currently, besides human safety concerns, the size of the gene of interest capable of being packaged within retrovirus vectors is limited to ~8 to 10 kbp of sequences. In summary, future studies may permit the development of gene therapy devices that harness the unique power of retroviruses, providing safe treatment of a variety of genetic diseases in humans.

6 Ubiquitous Nature of Mobile DNA Elements

Retroviruses are not the only DNA elements that have the potential to transduce their genetic information from cell to cell. As previously stated, yeast retrotransposons have the ability to move within the same cell using a similar replication and integration cycle as retroviruses. Retrotransposons exist also in the genomes of a large variety of fungi, plants, and vertebrates. For example in plants, the genome of maize (corn) is composed of ~50% retrotransposon elements. Many mobile DNA elements that are either similar or dissimilar to retroviruses can modify chromosome structure and function. Some of these elements are active, although most are inactive and comprise a large percentage of animal and plant genomes. These elements move within the cell and do not require an exterior envelope structure associated with retroviruses (Fig. 1). We are now just beginning to understand the ubiquitous presence of mobile DNA elements in nature relative to the evolutionary paradigm.

7 Perspectives

The study of retrovirus integration has far-reaching effects on human health. Retroviruses are of particular concern

and interest because of the obvious HIV-1/AIDS pandemic, and because they can potentially serve as tools for human gene therapy. The current clinically proven therapy for HIV-1/AIDS consists of combinations of drugs known as *highly active antiretroviral therapy* (HAART) to the viral catalytic enzymes. The use of HAART directed against the HIV-1 reverse transcriptase and protease has effectively reduced the virus loads in HIV-1 infected individuals with concurrent reduction of diseases and death rates. The emergence of HIV-1 strains that are resistant to these inhibitors necessitates development of unique antiviral drugs. Inhibitors to IN are in human clinical trials. The biological and biochemical studies of PIC and IN of all three retroviruses have aided scientists in identifying these new IN inhibitors. Hopefully, the future will bring retrovirus vectors that can function safely in human gene therapy. More information on human gene therapy including retroviral and other viral vectors is available at http://www4.od.nih.gov/oba/rac/clinicaltrial.htm.

Keywords

Action Spectrum
A method of analyzing the effect of different wavelengths of light on a biological response to characterize its spectral sensitivity and photopigment type.

Arabidopsis
Arabidopsis thaliana (mustard plant). A plant widely used in genetics research.

bHLH
Basic helix-loop-helix, a structural feature of many proteins capable of binding DNA.

Chromophore
The light-absorbing moiety of a photopigment.

Circadian Rhythm
A biological rhythm that persists under constant conditions with a period length of around 24 h. From the Latin "*circa*" and "*diem*," about a day.

Circadian Time (CT)
The subjective internal time of an organism under constant conditions. By convention, CT 12 corresponds to activity onset for a nocturnal species, whereas CT 0 designates activity onset for a diurnal species.

Clock Gene
A general term used to denote a gene involved in the normal functioning of the core oscillator of the circadian system (see text for details).

Clock-controlled Gene
A gene whose expression is regulated directly by the core oscillator mechanism.

Cyanobacteria
Photosynthetic bacteria, often called *blue-green algae*.

DD
Abbreviation for constant darkness.

Diurnal
An activity or process that occurs during the daytime (light).

Drosophila
Drosophila melanogaster (fruit fly). A common model organism in genetics research.

E-box
A nucleotide motif, CACGTG, involved in enhancing the expression of many clock genes.

Eclosion
Hatching or emergence of an adult insect from its pupal case.

Entrainment
The process by which a biological oscillator is phase locked to a rhythmic environmental stimulus such as the light–dark cycle.

Free-running
The endogenous rhythm exhibited by a circadian system under constant conditions.

LD
Abbreviation for a lighting regime composed of alternating periods of light and dark.

LL
Abbreviation for constant light.

Masking
The phenomena whereby an external factor directly affects the expression of an overt circadian rhythm.

Neurospora
Neurospora crassa (bread mold). A filamentous fungus commonly used in genetic research.

Opsin
The protein component of animal photopigments. Opsins utilize a vitamin A chromophore and possess a characteristic absorbance spectrum.

Oscillator
A system capable of producing a regular fluctuation of an output around a mean. In circadian biology, an oscillator often refers to the molecular mechanism within a cell capable of generating a self-sustained rhythm with a period ~24 h.

Overt Rhythm
An observable rhythm that is directly or indirectly regulated by the circadian clock.

Pacemaker
An anatomical correlate of an oscillator, capable of both maintaining its own oscillation and entraining additional oscillators.

PAS Domain
Sequence motif found in many clock proteins, often associated with protein–protein interactions.

Period
The regular time interval between phase points (reference points) on an overt rhythm.

Peripheral Oscillator
A term that has been used to refer to an oscillator located in tissues that are capable of regulating local circadian rhythms. Also referred to as a *slave oscillator*.

Phase
A specific reference point in the cycle of a rhythm; for example, the daily onset of sleep.

Phase shift
A single, persistent change in phase brought about by the action of a zeitgeber.

Photoentrainment
The entrainment of the circadian system by a light–dark cycle.

Photoperiod
The period of light and dark over a specific period, usually 24 h.

Photopigment
A molecule that is capable of transducing the absorbance of a photon into an intracellular response.

SCN
Suprachiasmatic nuclei. Paired nuclei within the basal hypothalamus that function as the circadian pacemaker in mammals.

State Variable
A term used in mathematical modeling of oscillators, referring to a quantity that changes with time. More generally, a term used to denote a variable essential for defining the state of a system. Sometimes applied to the essential components (genes/proteins) required to generate a circadian oscillator.

***Tau* (τ)**
The endogenous period of a free-running biological rhythm.

Temperature Compensation
A characteristic of circadian rhythms, whereby changes in temperature do not significantly alter the period. A Q_{10} close to 1.

Zeitgeber
''Time-giver,'' from the German, referring to an environmental signal capable of entraining a clock-driven rhythm.

Zeitnehmer
''Time-taker,'' from the German, referring to an output from the clock that can feed back to regulate the input pathway. The action of light on the clock is often gated by the clock itself. The rhythmic regulation of an input pathway can generate a rhythmic entraining stimulus even under constant conditions.

We are ruled by time and we need to know the time to tell us what to do. But the clocks that instruct us to wake, eat, and go to bed are unnatural. In our modern world, we are being driven by the energy states of an electron in the cesium atom and use machines to hack our day into hours, minutes, and seconds. Yet, despite the atomic clock, our bodies answer to another more persistent beat that probably started to tick shortly after life evolved. Embedded within the genes of us, and almost all life on earth, are the instructions for a biological clock that marks the passage of approximately 24 h. Biological clocks drive or alter our sleep patterns, alertness, mood, physical strength, blood pressure, and every other aspect of our physiology and behavior. Under normal conditions, we experience a 24-h pattern of light and dark, and our clock uses this signal to align biological time to the day and night. The clock is then used to anticipate the differing demands of the 24-h day and ''fine-tune'' physiology and behavior in advance of the changing conditions. Body temperature drops, blood pressure decreases, and tiredness increases in anticipation of going to bed. While, before dawn, metabolism is geared up in anticipation of increased activity when we wake. The past decade has witnessed remarkable progress in the understanding of circadian rhythms in many different organisms. Much of what we know of the molecules that make up our biological clockwork has been learnt from the fruit fly (*Drosophila*) and mouse. It is remarkable that species separated by hundreds of millions of years of evolutionary history are united by the ways in which they generate biological time. The understanding of the molecular basis of circadian rhythms is one of the first success stories arising from the genome sequencing projects, and is currently one of the best examples we have of how genes and their protein products give rise to complex behaviors.

1 Introduction

The term ''chronobiology'' is derived from the Greek (*chronos* for time, *bios* for life, and *logos* for study), and is used to denote the study of ''biological clocks'' within living organisms. These internal clocks exist in all eukaryotes and have been identified in some prokaryotes. Indeed, the possession of such a clock has been regarded by many as one of the signatures of a living organism. Biological clocks provide an organism with an internal representation of a timed and predictable environmental event such as the 24-h rotation of the earth and the consequent rising or setting of the sun, or the annual change of the seasons. Knowledge of these predictable events allows an organism to prepare in advance of the changed circumstances, and so avoid the dangers and exploit the advantages of the ''new'' environment. A biological clock can be considered to ''fine-tune'' an organism to its temporal niche. This advanced warning provided by the clock is necessary because different physiological or behavioral states cannot be switched instantly. For example, the transition from sleep to wake requires several hours in most mammals and involves the complete realignment of almost every biological system and process. If an organism waited to trigger its biology in response to a major change in environment, then valuable time would be wasted while physiology was realigned to generate an optimal performance. Peak performance is demanded by natural selection, where even modest advantages are translated into long-term evolutionary success. Thus, almost every cellular, physiological, or behavioral output is modulated to a greater or lesser extent by a chronobiological process. For the experimentalist, this presents a practical problem. We often undertake our studies at particular times of the day or night, and as a result, the data collected may not provide an accurate representation of events over the whole day. Furthermore, data collected at one time of day may not be comparable with data collected at other times. As shown in Fig. 1, body temperature, hormone levels, reaction times, alertness, and performance, and even our responses to medical treatment all show marked differences depending upon the time of day.

The constant temporal adjustment of physiology by an internal clock is somewhat at odds with the original concept of homeostasis as proposed by Claude Bernard and Walter Cannon. For them, and the several generations that followed, constancy was everything and deviations away from a ''set-point'' represented a breakdown in a homeostatic mechanism rather than an adaptive response to a changing environment. The teaching of biology and medicine has been dominated by the concept of an unchanging internal environment. Medical students have been expected to learn a vast range of physiological parameters that described the ''average human'' over a narrow temporal range. Blood pressure in a healthy individual is considered to be around 120/70, and yet at 06 : 00, it can drop as low as 60/30 in some healthy individuals. Similarly, body temperature is not always set at 37 °C, it reaches its peak around 20 : 00 and then falls by ~1 °C or more between 04 : 00 and 06 : 00 in the morning. Certain hormones, such as melatonin or growth hormone are very low during the day but are elevated at night, and the incidence of epileptic seizures increases dramatically at night (Fig. 1).

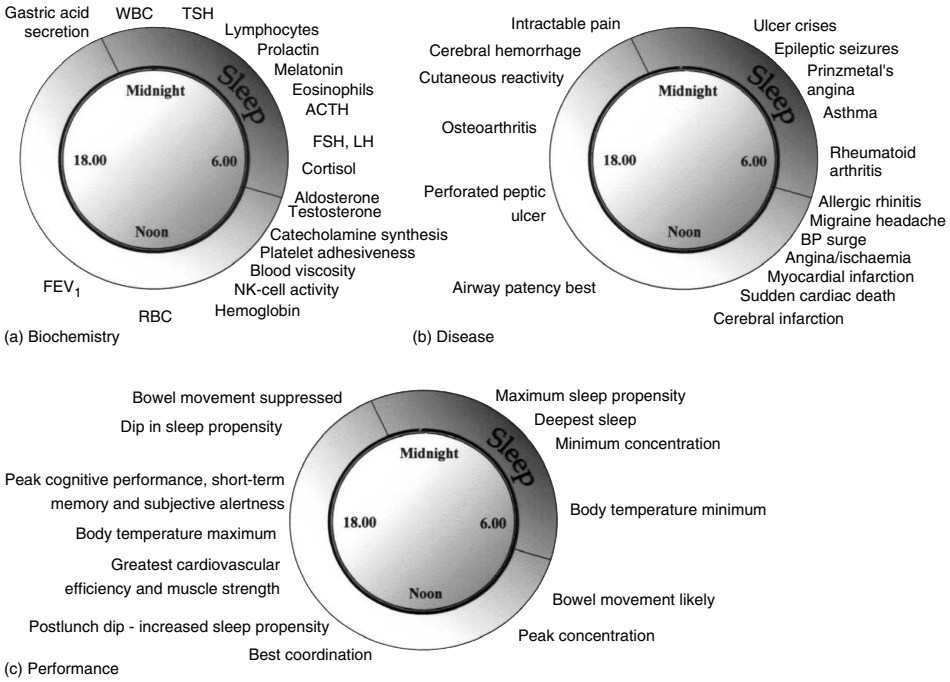

Fig. 1 Illustration of circadian rhythms in various aspects of human physiology, including (a) biochemistry, (b) disease incidence, and (c) performance. Times of peak incidence are approximate. Data taken from Smolensky, M.H. (1996) Chronobiology and chronotherapeutics. Applications to cardiovascular medicine, *Am. J. Hypertens.* **9**, 11S–21S and Carrier, J., Monk, T.H. (2000) Circadian rhythms of performance: new trends, *Chronobiol. Int.* 17, 719–732.

These lists of daily variations are endless, and even amusing, the preferred time for human sexual behavior in a recent survey reported in a popular magazine was 22 : 00. But what is often missed is that these lists contain critical information relating to the potential health and wealth of our species. Jürgen Aschoff, in his pioneering studies on human biological rhythms, made the point that an awareness of these changes is not only important for the design of specific clinical treatment paradigms but can also be used to help gauge the likelihood of accidents and performance-related mistakes in groups as diverse as nightshift workers, nurses, and fighter pilots.

After almost 100 years of detailed investigation, the study of biological clocks has come of age, and clock-driven changes in physiology are being incorporated into the mainstream teaching of biology and medicine. Although chronobiology has not yet been entirely embraced by the medical profession, clock-driven changes are no longer ignored. The concept of time-dependent variables is replacing the ''fixed set-points'' of former years, and while this knowledge is welcomed at one level, the life of the health care worker has become even more demanding. Another dimension of the body has to be taken into consideration – body time.

2
The Properties of Circadian Rhythms

The first person to study biological rhythms in an experimental context was the French astronomer Jean Jacques Ortus de Marian. His interest in the rotation of the earth led him to ask why the leaves of plants move up and down during each day in time with the 24-h rotation of the earth. In 1727, he placed a Mimosa plant in a cupboard and isolated it from the daily light–dark cycle, and noted that the plant still moved its leaves so that they drooped when it was night and were raised up during the day even though the plant had no direct contact with the light–dark cycle. He suggested that the plant had to have some internal or endogenous knowledge of the time of day. Some 30 years later, Henri Louis Duhamel reasoned that the Mimosa plants might have been responding to the daily change in temperature and so repeated the experiment in the constant light and temperature conditions of a salt mine. Duhamel found the same responses as de Marian, rhythmicity persisted under constant conditions. Approximately 100 years later in 1832, a Swiss botanist Alphonse de Candolle made the observation that under constant darkness the period of leaf movement was not exactly 24 h and varied slightly between different plants. Although this early work on *Mimosa*, and the movement of other plants, was pioneering, the rigorous investigation of biological rhythms began in Germany, with the studies of Erwin Bünning in the 1930s. Bünning worked on the bean plant *Phaseolus* and showed that leaf movement oscillated with a mean period of 24.4 h in constant darkness, and established one of the critical properties of biological clocks; when isolated from environmental cues, they persist with a period close to but never exactly 24 h. This near-24-h oscillation under constant conditions is known as the *free-running* rhythm of the clock. For example, the free-running period of a mouse is approximately 23.7 h, and so its activity will start a little earlier and earlier every 24 h under constant conditions. From the 1930s, free-running rhythms close to 24 h were demonstrated in very many different animals and plants, so that by 1959, a collective term was needed to describe such phenomena. Franz Halberg suggested that they should be called circadian (circa about, diem a day) rhythms, and the term has stuck. Circadian rhythms are not the only biological clock–driven rhythms observed in nature. Additional rhythms have been defined on the basis of their period under constant conditions and relatedness to environmental cycles. For example, circannual rhythms have periods of approximately one year, and have been best described in hibernating mammals such as the golden mantled ground squirrel, and circalunar or circatidal rhythms have periods of approximately 30 days and are found in many intertidal organisms. Our understanding of these other ''circa'' rhythms extends a little beyond the knowledge of their existence, and so all further discussion of biological clocks in this article will be confined to those generated by a circadian clock.

In parallel with the demonstration of free-running rhythms, work in the 1950s by Karl von Frisch who studied bees and Gustav Kramer working on migratory birds showed that animals must utilize an internal clock. Both studied time-compensated sun compass navigation. Bees and birds will orientate their movements by using the sun as a navigational reference point. Bees will forage for nectar and locate different plants

at specific times of the day, and birds will migrate at different times of the year. On average, the sun moves across the sky at 15° per hour, and both groups of animals were shown to consult an internal clock to compensate for this movement. For example, in the case of birds migrating north in the spring, they will orientate so that the sun is 90° to the left at 09 : 00, straight ahead at 12:00, and 90° to their right at 15:00. For reasons that are not exactly clear, these studies showing time-compensated orientation had much more of an impact on biologists, convincing of the existence of endogenous clocks than the demonstration of free-running rhythms. By the mid-1950s, the stage was set for a more formal description of circadian rhythmicity, and onto this scene emerged a man of remarkable intellect, Colin S. Pittendrigh. He not only pioneered the study of circadian rhythms in the fruit fly *Drosophila* but also applied his reasoning to a broad range of different animal models. Pittendrigh's work examined the nature of free-running rhythms, but his major contribution was that he went on to characterize/identify two further fundamental properties of all circadian clocks; entrainment and temperature compensation.

Biological clocks are temperature compensated, that is, their period is more or less constant irrespective of environmental temperatures. The clock of ectotherms would be useless if it were not. Circadian clocks do not obey the Q_{10} rule, a rise of 10 °C does not double the period of the oscillation. This issue of temperature compensation was a major point of controversy in the early days of biological clock research. Researchers such as Frank Brown argued that no biological process could possibly act independently of temperature and the constancy of the circadian period under different temperature conditions must mean that these rhythms were driven by some unknown environmental factor related to the earth's rotation. One of Pittendrigh's experiments on this topic showed that *Drosophila* would always emerge from their pupal case (eclosion) at dawn irrespective of environmental temperatures. Although his observation has now been duplicated in many different species using multiple circadian outputs, our understanding of how temperature compensation is brought about is little more than guesswork. By contrast, the mechanisms that adjust biological clock time to environmental time (entrainment) are far better understood.

A biological clock is of any use only if internal clock time is adjusted to environmental time. The classic example of a mismatch between biological and environmental time is ''jet lag.'' In the natural environment, many factors could set or ''entrain'' circadian rhythms to a specific phase of the 24-h rotation of the earth. Light, temperature, food availability, or even social contact could indicate the time of day. However, only those factors that provide the most reliable indicator will be selected by evolution to entrain circadian clocks, and for most species, the 24-h change in the quality of light at dawn and dusk provides this signal or zeitgeber (time signal). In the absence of light, other signals such as temperature or food can act as zeitgebers, but if animals are exposed to conflicting signals such as light and temperature, light will invariably be selected as the zeitgeber.

Pittendrigh was one of the first to make a systematic study of entrainment. He explored the effects of short pulses of light on free-running rhythms in a

variety of animals, including *Drosophila*, maintained in constant darkness. He showed that light had different effects on the clock at different phases of the circadian cycle. As the animals were kept under constant darkness, he used the phase of activity of the animal to determine the position of the clock. In a nocturnal species, activity onset was considered to indicate the beginning of the night and designated circadian time (CT) 12 (the subjective night would span CT 12–24), while in a diurnal species, the start of activity was considered to signal dawn and designated CT 0 (the subjective day would span CT 0–12). Pittendrigh observed that light pulses given to free-running animals during their subjective day would have no marked effect on the clock, while light during the first half of the night (CT 12–18) would delay the clock – the animal would start activity later the next day. By contrast, light given during the second part of the night (CT 18–24) would advance the clock – activity would start earlier the next day. Pittendrigh studied a range of both nocturnal and diurnal species, and remarkably, all showed the same basic ''phase response curve'' (PRC) to light (Fig. 2), although the precise shape would vary between species.

In all organisms studied to date, light around dusk will delay the clock and light around dawn will advance the clock, and in this way, activity is broadly aligned to the expanding and contracting light–dark cycle throughout the year. The PRC model of entrainment has been helpful in searching for entrainment mechanisms and the molecular components of the circadian system (see below). However, it does not provide a complete description of entrainment. We do not fully understand how light intensity, wavelength, the phase of exposure, the length of the free-running period, the magnitude of the advances and delays, or even how photic and nonphotic cues might interact to generate stable entrainment.

The existence of circadian rhythms and their basic properties (persistence under constant conditions, temperature compensation, and entrainment) were established by the 1970s, and interest began to shift to more mechanistic questions. If there is a clock, where is it? How does it work? How does light synchronize the clock to local time? Is there just one clock? How did they evolve? The answers to these questions are still emerging and are outlined in the following pages. Progress over the past few years has been spectacularly rapid, and currently, there is perhaps no better example of how patterns of gene expression and protein interactions generate a specific set of behaviors in highly diverse groups of organisms.

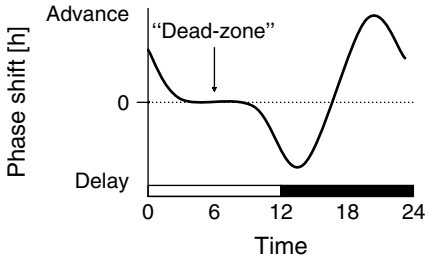

Fig. 2 Phase response curve of the circadian system, illustrating the response to light administration at different phases of the circadian cycle. Advances correspond to an earlier activity onset, whereas delays correspond to a later activity onset. The ''dead zone'' represents a period of relative insensitivity to light.

3
The Mechanisms of Circadian Rhythmicity

Early on in the hunt for circadian mechanisms, a conceptual framework emerged that compartmentalized the circadian system of all organisms into three basic elements: the input or entrainment pathway, the core circadian oscillator, and an output pathway (Fig. 3). While this depiction has turned out to be overly simplistic, largely because different molecules often span an input/oscillator or oscillator/output function, it has nevertheless provided a valuable model to develop experimental questions and compare the various elements of circadian systems in different organisms. For this reason, we have organized the information below using the entrainment > oscillator > output format, as diagrammed in Fig. 3, and have considered the circadian system of six model organisms, *Drosophila*, mouse, zebrafish, *Neurospora, Arabidopsis,* and cyanobacteria. We have selected these species to provide taxonomic breadth to the discussion of how the molecular clock might be generated and because rightly or wrongly, these species are the focus of genomic analysis.

3.1
Drosophila

Drosophila has proved to be a critical organism in the study of many biological processes, but few more so than the circadian clock. Studies in the fly have formed the historical backbone of most of what we know about circadian clocks, and, as such, no review can cover all of the contributions made by this organism. The power of *Drosophila* forward genetics and the use of mutant screens to identify molecules involved in a complex biological process, about which one has no *a priori* knowledge, is best exemplified by the use of the fly to examine clock function. Most of the critical clock genes in animals have been identified in this organism, as the following sections demonstrate. Furthermore, once a gene has been isolated, research on *Drosophila* has helped frame a set of questions that have been used by the whole field of circadian biology to help establish whether a gene encodes a real component of the clock. These questions can be summarized as follows: (1) Do mutations in the gene cause changes in period or arrhythmicity of output rhythms? (2) Does the abundance or activity of the gene oscillate with the same period as the overt rhythm? (3) Does the constitutive expression of the gene result in arrhythmicity of the overt rhythm? (4) Do entrainment signals modify levels or patterns of gene expression? (5) Can the protein product alter the expression of its own gene? As we shall discuss below, many ''clock genes'' do not fulfill all of these criteria, but addressing these questions has provided a useful

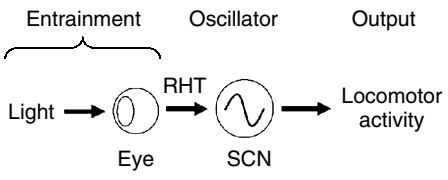

Fig. 3 Basic model of circadian system. A schematic depiction of the components of a circadian system, including an environmental input, an oscillator, and clock-controlled output. The mammalian system is shown as an example, with light-entrainment signals detected by the eye, providing an input to the SCN oscillator via the retinohypothalamic tract, and the SCN driving circadian patterns of locomotor activity.

experimental framework for defining their possible function(s).

3.1.1 Entrainment

A clock is not a clock unless it can be set to local time. So how does the *Drosophila* clock detect light? In a larger animal, such as a rodent, one would begin to answer such a question by performing lesion studies, physically removing the structures likely to be involved. In a sense, this is also exactly what one does with *Drosophila*, but instead of using a scalpel, one uses the identification of specific mutants. The identification of mutant flies that lack or have modified circadian light responses is a very powerful approach. This approach is made even stronger when combined with another powerful tool for the examination of light responses in general, the generation of action spectra. All photopigments have distinct light absorbance characteristics, peaking at a particular wavelength, and acting as a ''spectral fingerprint'' that can be used to distinguish between the various types. By determining the specific wavelengths that optimally regulate/activate a particular response, usually entrainment or phase shifting in a circadian experiment, an action spectrum is generated and compared to the absorbance profiles of known photopigments. This comparison is a critical step in identifying the light-detecting molecules involved in a particular pathway.

Action spectra have been generated in *Drosophila* from as early as 1969 in *D. pseudoobscura* through to 2001. Over this 32-year period, a range of responses have been examined, including phase shifts of eclosion and locomotor behavior, and a surprising range of peak photosenstivities have been reported. Some of the reasons for this variation will become apparent later in this section. An apparently straightforward question might be, does *Drosophila* use an opsin/vitamin A- or non-opsin-based photopigment? An examination of phase delays in the eclosion rhythm showed a number of peak photosenstivities, mainly in the ''blue'' at 457 nm, but also around 375, 435, and 473 nm. The lack of a typical ''smooth'' opsin/vitamin A action spectrum was more suggestive of a flavoprotein response. This argument was supported by studies in which flies, deprived of carotenoids in their diet and showing a marked decline in the sensitivity of normal visual light responses, failed to show any significant alteration of their circadian eclosion. By contrast, when action spectra were generated for phase shifts of the locomotor rhythms, peak sensitivities were recorded around 500 nm, and these curves extended into the ''red'' region of the spectrum. These data fit more precisely with results that would be predicted if an opsin/vitamin A–based photopigment was involved in the circadian light response.

The results for the wild-type fly are surprisingly complex, with data supporting a role for both opsin- and non-opsin-based pigments. Some of this complexity might be due to the wide range of light-detecting structures found in insects, and specific mutants, lacking particular photic structures, will be required to clarify this situation. Insects like *Drosophila* possess two large compound eyes, as well as a variety of extraocular photoreceptive structures including several ocelli, and the relatively recently described H-B eyelets (after Hofbauer and Buchner). It may be likely that additional, as yet unidentified, light-responsive structures also exist. The H-B eyelets are of considerable interest. These structures, each composed of four photoreceptor-like cells and expressing the *Drosophila* rhodopsin gene *Rh6*, as well as

arrestin, have direct projections to specific ventral lateral neurons (LNv) within the brain of the fly. These LNv cells are of particular importance in the *Drosophila* circadian system, as they are clearly responsible for generating the rhythm in locomotor activity, and as such are seen as the ''master'' pacemaker within the fly (see below). This direct link between master clock and photoreceptive structure, though correlative, is strongly suggestive of the fact that these H-B eyelets may play a role in clock entrainment.

The results from several *Drosophila* mutants help confirm the importance of these H-B eyelets. The mutant fly *sine oculis*^{1} lacks compound eyes, but retains the extraocular photoreceptive structures, the H-B eyelets. The action spectrum from these mutants revealed two distinct peaks of sensitivity at 420 and 480 nm. An additional loss of function mutant called *glass*^{60j} (as well as the double mutant *sine oculis*^{1}:*glass*^{60j}) produces an animal that lacks all compound eyes and H-B eyelets. Action spectra performed on these mutants produced only one peak of sensitivity at 420 nm. These experiments clearly demonstrate that the H-B eyelets are involved, in part, in light-induced phase shifts, responding to light primarily at 480 nm. This peak sensitivity is quite close to the absorbance of 515 nm reported for the *rhodopsin 6* (*Rh6*) gene found to be expressed in these cells. Remarkably, however, the glass mutant is still able to show light-dependent phase shifts in activity, even though it lacks all known ocular and extraocular photoreceptive structures. There must be additional light-responsive cells in the fly and these must have a peak of sensitivity in the region of 420 nm.

An apparent answer to this problem was solved by the discovery of the blue light–absorbing proteins, the cryptochromes, and the isolation of another *Drosophila* mutant *cry*^{baby} (*cry*^{b}). The cryptochromes are flavoproteins, using a pterin or flavin (FAD) as a cofactor, which appears to act as a primary chromophore, absorbing light primarily in the ''blue'' wavelengths. These molecules are closely related to the DNA repair enzymes, the photolyases, and as such have not only an ancient evolutionary history but are expressed widely in a number of cell types. The *cry*^{b} mutant fly was discovered as an arrhythmic animal in terms of *period* and *timeless* gene expression (see Sect. 3.1.2), as measured in *period*-luciferase transgenic animals. This lack of rhythmicity could represent a defect in their central clock mechanism, or a lack of entrainment (due to lack of photosensitivity), and subsequent asynchronous clock gene oscillations within the animal. These flies also cannot phase shift in response to short light pulses and fail to become arrhythmic in constant light, as do wild-type flies. Furthermore, these behavioral defects in the *cry*^{b} flies can be partially overcome by specifically overexpressing wild-type *cry*$^{+}$ in the lateral neurons. This important result shows that these neurons themselves are directly light responsive, and that cryptochrome can act intracellularly as part of a local photoentrainment pathway. However, these mutant flies are still capable of entraining to a light–dark cycle, as are the molecular oscillations within the lateral neurons. Also, cryptochrome clearly appears to have a role in the mechanism of peripheral oscillators outside of the lateral neurons (see below). Cryptochrome is clearly not the only element of the photosensory pathway leading to entrainment of the circadian clock. Only when the double mutant *glass*^{60j}:*cry*^{b} is generated, are totally clock-blind animals produced.

These double mutants are not capable of showing phase shifts or entrainment, as measured by a variety of circadian clock parameters. The amazing conclusion is that *Drosophila* use a range of independent mechanisms to set the circadian clock. Clearly, a cryptochrome-dependent mechanism within the lateral neurons is capable of responding to light and adjusting the clock. Also, the H-B eyelets respond to light, probably using an opsin/vitamin A–based molecule (*Rh6*). Furthermore, there also appears to be an influence of photoreceptors within the compound eyes on resetting. These multiple pathways into the clock give *Drosophila* great flexibility in terms of their circadian light response, and may extract much more information about the environmental lighting conditions than we initially expected. Different pathways appear to entrain different aspects of the circadian system, with, for example, the cryptochrome-dependent pathway being mainly involved in entraining the evening peak of activity, whereas retinal and extra retinal structures primarily influence the morning peak. One major advantage of such a system is that these animals may be able to determine more than simply the presence or absence of light, but actually sense whether they are seeing ''morning'' or ''evening'' light, a very useful feature for a clock-related photosensory system.

3.1.2 Oscillator

The first mutant screens in *Drosophila* were started as far back as 1968 in Seymour Benzer's laboratory, and over the following 35 years, forward genetic efforts have provided us with most of what we know about the clock mechanism. The first circadian fly mutant was isolated in a pupal eclosion screen and identified as flies that either hatched randomly with respect to the light–dark cycle (aperiodic) or emerged earlier or later than expected from their pupal cases. These mutations mapped to the same locus, named *period* or *per*, and when placed into constant darkness, three distinct mutant alleles were identified, per^S (Short) with a free-running period of ~19 h, per^L (Long) with a period of ~29 h, and per^0, which are aperiodic.

It was a further 16 years until the *period* (*per*) gene itself was isolated and a couple more until the sequence was published. The PERIOD (PER) protein contains what has become known as a PAS domain, named after the proteins in which they were first identified: *Drosophila* PER, the human aryl hydrocarbon receptor nuclear translocator (ARNT) and the *Drosophila* single-minded protein (SIM), and is a stretch of amino acids thought to be involved in protein–protein interactions. The PER protein, therefore, has a partner as we shall see below. PER in *Drosophila* lacks a basic helix-loop-helix (bHLH) DNA binding domain, and as such, does not appear to be a DNA binding/transcription factor. Oscillations of protein and mRNA were observed with an interesting 4- to 6-h delay between the peak of transcript and the subsequent peak in PER protein. Furthermore, constitutive overexpression of the PER protein inhibited cycling of the period transcript, and so a negative feedback loop between protein and gene expression was strongly suggested.

PER was clearly an important and central clock component, and it remained the only one for quite some time. Then, finally, the protein partner of PER was discovered in 1995. Gekakis and colleagues isolated a protein called *TIMELESS* (TIM) through use of a yeast two-hybrid screen, in which PER-interacting proteins could be identified. At about the same time, the *timeless* (*tim*) gene was positionally cloned

and sequenced by a second group as part of an analysis of the *timeless* mutant fly, which showed a loss of behavioral and *per* gene rhythmicity. Then there were two, but how the clock might work still required the isolation of at least three more critical genes.

For once, *Drosophila* lagged behind the mouse in the identification of novel clock components. In 1997, the first vertebrate clock gene, *Clock*, was cloned following a large-scale mutant screen in the mouse (see Sect. 3.2.2). Within a year, however, a homolog of mouse *Clock, dClock (Clk)*, had been isolated as part of an ongoing large-scale clock mutant screen in *Drosophila*. The homozygous *dClock* mutant flies were arrhythmic in terms of locomotor behavior and eclosion, and perhaps, more interestingly, showed very low levels of both PER and TIM protein. As in the mouse CLOCK protein, dCLOCK (CLK) is a bHLH transcription factor, which also possesses a PAS domain. A protein partner had already been discovered for mouse CLOCK, called BMAL1, and it was not long before an equivalent gene was identified in *Drosophila*. The *Drosophila* homolog is known as *cycle* (*cyc*) and again was identified as an arrhythmic fly in a *Drosophila* locomotor screen. As with mammalian BMAL1, CYCLE (CYC) is a bHLH PAS domain–containing protein that forms a heterodimer with CLK. The *cyc* mutant also shows reduced levels of TIM and PER protein expression. Considerable similarity is clearly apparent between the putative clock mechanism of both *Drosophila* and mammals (see Sect. 3.2). CLK and CYC bind to regulatory elements, called E-boxes (CACGTG), within the upstream promoter regions of *per* and *tim*. This positive transcriptional activation increases the transcript levels of both *per* and *tim*, and explains the low levels of both seen in the *Clk* and *cyc* mutants.

One additional *Drosophila* clock mutant was also discovered in 1998. Three alleles of the *double-time* (*dbt*) mutant fly were identified, with a short- and long-period form (dbt^S and dbt^L). The third allele dbt^P was lethal in the pupal stage, but eliminated oscillations of PER and TIM proteins in the larva. Mapping and cloning of this mutation revealed it to be a homolog of mammalian casein kinase I epsilon. In the dbt^P mutation, PER protein accumulated in a hypophosphorylated form, suggesting that DOUBLE-TIME (DBP) might well be involved in PER phosphorylation and potentially in its degradation.

How might the clock components, described so far, actually fit together to generate a circadian oscillation? Though additional clock mutants have been discovered, some of which will be discussed below, the core mechanism can be deduced from research on the elements described above (Fig. 4). The *per* gene appears to be activated in the afternoon, as a consequence of the binding of the positive transcriptional activators CLK and CYC, acting as a heterodimer on E-box elements within the *per* promoter. However, the PER protein does not begin to accumulate for some time. The reason for this is believed to be a consequence of the action of the casein kinase, DBT, which phosphorylates PER monomers and targets them for proteolytic degradation. Recently, an F-box/WD40-repeat protein, called *SLIMB*, has been shown to interact in a preferential manner with hyperphosphorylated PER and target it for ubiquitin-proteosomal degradation. PER is protected from this degradation only when sufficient amounts of the TIM protein begin to accumulate. The PER-TIM heterodimer then begins to

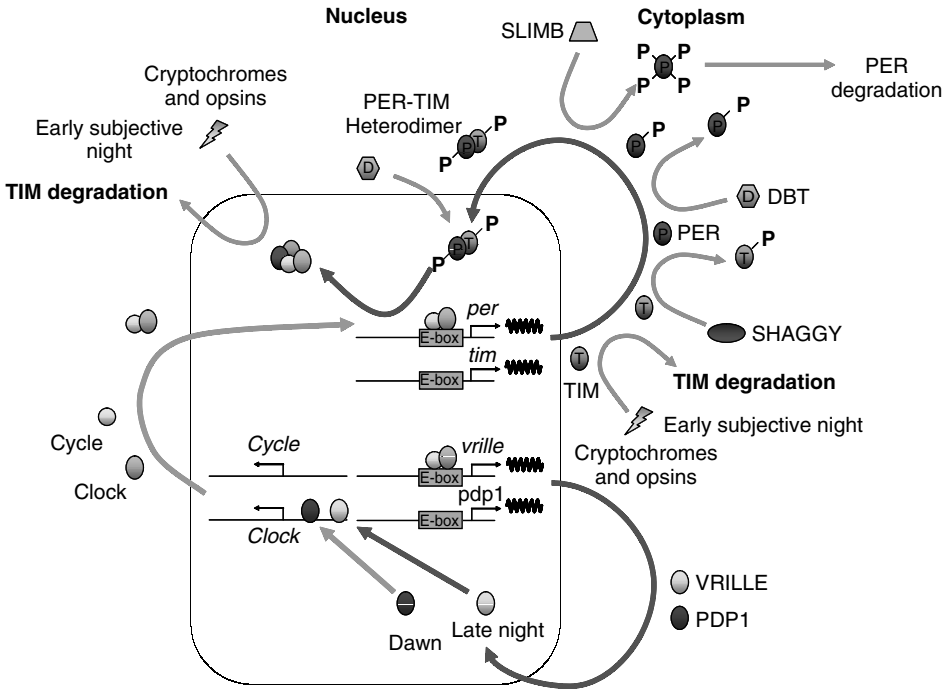

Fig. 4 The *Drosophila* circadian clock appears to be composed of two interacting molecular loops. The clock proteins, CLOCK and CYCLE, act positively on E-boxes within the promoters of the genes *period* and *timeless*. PER and TIM proteins begin to accumulate in the cytoplasm but with an approximate 6-h delay between the peaks in transcript levels and those of the corresponding proteins. PER monomers are phosphorylated by the casein kinase, DOUBLE-TIME, which targets these proteins for degradation. With the increase in TIM protein and the formation of PER-TIM heterodimers, PER is stabilized, and the amount of both proteins begins to accumulate. TIM is phosphorylated by SHAGGY (GSK3), which may play a role in regulating the nuclear entry of PER and TIM. Upon nuclear entry, PER (as a protein complex) binds to CLOCK-CYCLE, repressing their positive transcriptional activity. In this way, PER and TIM feed back negatively to inhibit their own expression. Expression of the *clock* gene also oscillates in *Drosophila*. This oscillation is thought to be due to the positive action of the PAR domain protein PDP1 and repression by the protein VRILLE. The phasing of the rhythms of PDP1 and VRILLE differs, allowing for the generation of a *clock* transcript oscillation. In turn, *vrille* and *pdp1* promoters contain E-boxes, and so these genes are rhythmically expressed as a consequence of the action of CLOCK and CYCLE. The interaction of these proteins and genes represents a second but linked circadian molecular oscillation in *Drosophila*. Entrainment of the molecular clock occurs through both opsin and cryptochrome-dependent pathways. Light exposure results in the degradation of TIM (see text for details).

accumulate in the cytoplasm of the clock-containing cells.

TIM protein itself undergoes rhythmic phosphorylation. The kinase thought to be responsible for this posttranslational modification is *Drosophila* SHAGGY (SGG), an ortholog of the mammalian glycogen synthase kinase-3 (GSK3). GSK3 has been shown to have an essential role in mammalian development, but overexpression of *Drosophila shaggy* (*sgg*) in particular tissues shortens the circadian

free-running period. Mutations in *sgg*, reducing its levels, cause a lengthening of period and reduced TIM phosphorylation. This change in period is thought to be brought about by an alteration in the next critical event in the circadian cycle, the nuclear entry of the PER:TIM heterodimer. The overexpression of SGG clearly advances the timing of nuclear entry of this complex and may explain the ''faster'' running clock. A similar role may also be played by the phosphorylation of PER by casein kinase, as the dbt^S mutation delays the apparent nuclear accumulation of PER protein. In the mid-subjective night, the PER:TIM heterodimers enter the nucleus, possibly in combination with DBT and perhaps other proteins, as a large protein complex.

The nuclear entry of this complex is a critical step in the negative feedback part of the circadian loop, as it now brings the positive transcriptional regulators, CLK and CYC, into close physical proximity with the negative regulators, PER and TIM. The negative repressive action of PER:TIM is thought to occur as a consequence of direct physical interaction between the two protein complexes, which reduces the ability of CLK:CYC to bind to the E-boxes within the *per*:*tim* promoters. Of course, for the positive action of CLK:CYC to be reactivated and a new cycle to begin, this nuclear repression must be removed. How this occurs is not yet totally clear. However, it is known that the removal of TIM from the negatively acting protein complex is a critical step and that this may involve the action of SGG in some manner. The TIM protein may inhibit the direct action of DBT in phosphorylating PER, and so a reduction in TIM would lead to an increase in PER phosphorylation. This increased phosphorylation may then allow for degradation of PER protein in the nucleus and a removal of the repression on CLK:CYC. With the repression removed, these positive transcriptional regulators can act again back on the DNA to increase *per* and *tim* transcription, beginning the cycle anew. As light reduces PER and TIM levels via cryptochrome (see below), this results in a derepression of *per* and *tim* transcription, providing a mechanism by which light may influence the phase of the molecular clock. These processes are summarized in Fig. 4.

The above description is, in some ways, a simplified description of what is thought to occur in constant darkness (DD), but circadian clocks are rarely exposed to DD in living animals. The rhythmic environment, and exposure to light, is obviously essential for setting the clock, as has been discussed above. However, circadian oscillations are not only set to LD cycles but appear more ''robust'' with the molecular components showing a higher amplitude of oscillation. Light probably provides a ''tonic drive'' to these molecular clocks as well as setting their phase. But the critical question remains: how is the *Drosophila* molecular clock entrained to a light–dark cycle? The main action of light on central clock components is the light-dependent degradation of TIM via the proteosomal degradation pathway. As TIM is required for the stabilization of PER, it seems likely that the reduction in TIM levels by light will increase PER phosphorylation (as discussed above) and its targeted degradation.

Also, as discussed under ''entrainment'' (Sect. 3.1.1), CRY appears to play a critical role in the light-dependent degradation of TIM. This can be clearly shown in cry^b mutant *Drosophila*, lacking functional cryptochrome, in which high levels of stable TIM protein can be detected under an LD cycle. The typical light-dependent

TIM degradation is abolished in such mutants. Thus, the current model for molecular entrainment and an explanation for the PRC (Fig. 2) suggests that in the late subjective night, a pulse of light will lead to the degradation of TIM within the nucleus at an advanced circadian phase. This TIM degradation, along with that of destabilized PER, should remove the negative regulation on CLK and CYC. These positive transcriptional activators are then free to act again on the promoters of *tim* and *per* at an earlier phase and as such cause a phase advance of the circadian rhythm. The explanation for the generation of phase delays is a little less convincing, but the same light-dependent degradation of cytoplasmic TIM occurs in response to light pulses given in the early subjective night. However, at this time in the cycle, transcript levels for *tim* are high and so new TIM protein rapidly replaces that which is degraded, an event that is thought to generate a delay in the timing of the rhythm by extending the inhibition of CLK and CYC. What is clear, however, is that a complex balance of protein levels and protein interactions, between positive and negative acting factors, is essential to determine the resulting phase of the clock following exposure to light.

The interaction of CRY and TIM, as well as that of CRY and PER, in response to light pulses, is itself a complex event. It has been proposed that a currently unknown nuclear factor exists that binds to CRY in the dark, with the effect of preventing an interaction between CRY and the two central clock proteins. Upon light exposure, this nuclear factor is displaced from CRY, allowing for the critical interaction with TIM, which eventually leads to TIM degradation. If there was only one ''unknown'' nuclear factor, we might all sleep easy, but in reality, many more components of the light-entrainment pathway undoubtedly remain to be discovered in *Drosophila*.

The *Drosophila* clock seems also to have a second transcriptional loop that runs in parallel with the PER/TIM loop described above. In *Drosophila, Clk* transcript levels show a circadian oscillation, unlike the situation for *Clk* in the mouse. This raises the obvious question, how might *Clk* transcription itself be regulated? The oscillation in *Clk* transcript peaks in the early day, and is antiphasic to that of *per* and *tim*. A particular mutation in *Drosophila* appears to directly influence the levels of *Clk* expression. A loss of one copy of the gene *vrille* (*vri*) causes a shortening of circadian period, while overexpression tends to lengthen period. The VRILLE (VRI) protein itself oscillates, with a peak in expression corresponding to the trough in *Clk* transcript levels, and overexpression of *vri* causes suppression of *Clk* transcription through direct action on the *Clk* promoter (Fig. 4). VRI is the active repressor of *Clk* transcription. However, a related protein PAR domain protein 1 (PDP1) appears to be the positively acting transcriptional activator of *dclock* transcription. Heterozygous *pdp1* null mutant flies show a lengthening of circadian period, and amounts of *Clk* transcript fall to very low levels in homozygous null *pdp1* mutant flies. Crucially, the timing of the rhythms of the repressor VRI and the activator PDP1 at both the RNA and protein levels are temporally separated, allowing for differential temporal effects on *Clk* expression. It is interesting that both genes appear to be positively regulated by CLK:CYC themselves. So, a second circadian transcription–translation negative feedback loop appears to exist in *Drosophila* in parallel but linked to the PER/TIM loop described above. In this second loop,

CLK:CYC increases the transcription of *vri* and *pdp1*. VRI then feeds back negatively to shut down expression of *Clk*, while PDP1 acts on the *Clk* promoter to stimulate its transcription. The functional reasons for a second loop are not immediately clear. However, a consequence of such a system may give the circadian oscillation an added robustness and accuracy over the length of many circadian cycles. Of course, it also provides additional areas for clock modulation and entrainment possibilities through a range of environmental stimuli.

A molecular basis for temperature compensation in the clock mechanism has been suggested by a polymorphism identified in the *Drosophila per* gene. The two major variants demonstrate a different geographical distribution related to the animal's ability to maintain a circadian period at different temperatures. Furthermore, the identification of a thermosensitive splicing event that occurs in the 3′ untranslated region of the *per* gene, suggests a temperature-sensitive switch in the regulation of *per* expression. These studies provide fascinating clues to the molecular mechanisms underlying the temperature compensation of circadian rhythms.

3.1.3 Output

The two assays used in most *Drosophila* mutant screens to identify novel clock genes have been locomotor activity and eclosion from the pupal case. Both of these behaviors are under strong circadian clock control. In the case of locomotor behavior, it is clear that the clocks residing within the lateral neurons of the fly brain are critical for the timing of these events. Outputs from these lateral neurons are clearly essential for providing the correct temporal drive to locomotor centers within the fly brain. One gene involved in the timing of eclosion is the clock-controlled gene *lark*. Mutations in this gene cause very early emergence from the pupal case, advanced eclosion. However, no effect is detected during the period of circadian locomotor behavior. LARK protein oscillates, even in constant darkness, but not in *per* null mutant flies, demonstrating the importance of the clock in its regulation. Expression is restricted to a number of neuropeptide-containing neurons in the ventral nervous system, which are believed to play a critical role in the regulation of pupal eclosion.

One clock-controlled gene of particular interest is *takeout* (*to*). This gene is activated in flies under starvation conditions but not in flies lacking a functional clock. In some way, the circadian clock is necessary for this stress response to lack of food, and these mutants not only die more rapidly than wild-type flies but also show altered locomotor rhythms. There is clearly an interplay between the clock mechanism and the metabolic condition of the fly. This, of course, makes a great deal of sense. If the fly is in a state of metabolic stress (starvation), then obviously the individual will need to alter its locomotor pattern in order to search for food. The relationship between circadian clock and metabolic state is undoubtedly of great importance, an idea that is supported by studies on food restriction and entrainment of peripheral clocks in the mouse (see Sect. 3.2.3).

As we shall see in almost all of the other clock model systems discussed below, the use of modern genomic approaches, microarray, and DNA "chips" has been applied to the study of clock-regulated genes in *Drosophila*. Several groups have performed such analysis, and a wide range of rhythmic genes have been identified. Microarray studies in *Drosophila* have demonstrated very little agreement, highlighting technical problems with transcriptome

analysis. The inconsistency between these studies may be due to factors such as the specificity of the tissue under analysis, lack of biological replication, as well as the different levels of stringency applied during data analysis. An interesting finding of microarray studies on clock gene mutants (*dClock*, *dper*, and *dtim*) is that the expression level of many nonrhythmic genes is also affected. This suggests that these genes may also possess nonclock functions, rather than being dedicated solely to circadian rhythm generation. However, a wide range of cellular and physiological processes within the fly have been implicated as being under clock control, including aspects of metabolism, olfaction (sensory function), learning and memory, immune function, and so on. One of the great pleasures of circadian clock research is being able to torment one's colleagues in other fields by asking them to repeat all of their experiments in the middle of the night!

Drosophila not only possess circadian clocks in the lateral neurons of the brain but apparently light-responsive clocks also exist throughout the tissues of their body, a fact that is also true in zebrafish (see Sect. 3.3 and 5.0). What these peripheral clocks actually regulate in the fly is not absolutely clear. However, one excellent example of the independent function of a peripheral pacemaker is in the control of the olfactory system in the antennae of the fly. An electrophysiological analysis of the antennal response to food odors showed a circadian rhythm in sensitivity. This response continued in cultured antennae, demonstrating its independence from central clock control. Of some interest is that this oscillation is lost in cry^b mutant flies. As described in the beginning of Sect. 3.1.1, cryptochrome is thought to play a role in light detection and entrainment of the central circadian clock (amongst numerous other functions). However, in the periphery, the role of cryptochrome appears to be much more as a clock component rather than a photopigment, as is the case in the mouse. This strongly suggests that there are interesting differences in the clock mechanism between central and peripheral pacemakers within the fly. The antennal response is only one example of a clock-controlled physiological event in *Drosophila*. Over the next few years, as our focus turns away from the mechanism of the central clock, it is undoubtedly true that many more interesting aspects of clock-controlled processes will be discovered.

3.2 Mouse

The identification of the master circadian pacemaker of the mammalian circadian system has followed the classical approach in the neurosciences, starting with anatomy, followed by lesions, then transplantation to restore function, and finally *in vitro* and *in vivo* analysis. One of the major goals of neuroscience is to identify the anatomical substrates of specific behavioral control systems. This has proven frustratingly difficult in many cases, but the achievement of locating the mammalian master pacemaker is one of the success stories.

Curtis Richter's seminal contribution to chronobiology was to help find the location of the mammalian clock. He conducted a heroic series of experiments to confirm first of all that it was the brain that housed the clock and second, to try and establish where exactly it was in the brain. Richter removed adrenals, gonads, pituitary, thyroid, pineal, and pancreas. It was only when he turned to the brain that he

was able to produce arrhythmia. He made over 200 studies, investigating what happened if he damaged the rat brain and measured the effect of the lesion on the rat's locomotion, feeding, and drinking behaviors. In 1967, Richter reported that lesions in the front part of the hypothalamus of the brain eliminated multiple behavior rhythms. But he could not get any closer. In the early 1970s, Friedrich Stephan and Irving Zucker linked the observations that the estrus cycle was dependent on a small part of the brain in the anterior hypothalamus and that there was circadian control in the timing of hormone release. By careful lesioning in the frontal part of the hypothalamus, they identified a small paired cluster of cells known as the *suprachiasmatic nuclei* (*SCN*) as critical elements in organizing rhythms of behavior such as drinking and locomotion. At the same time that Stephan and Zucker were performing lesions, Robert Moore was using a different approach to find the clock. Many studies had shown that there was an intimate relationship between the clock and light. Moore's approach was to follow the light path as it came in through the eye and see where it went. In 1972, he and his coworkers injected radioactive amino acids into the eyes of rats. They followed the tracer molecules as they traveled from the eye, through the optic nerves, and concentrated in the SCN as well as the known visual structures. The newly found pathway from the eye to the SCN was called the *retinohypothalamic tract* (*RHT*). When Moore lesioned the SCN, there was a loss of the circadian rhythm of the hormone corticosterone. Between them, Richter, Moore, Stephan, and Zucker had established that removing the whole of the SCN (but not just a part of it) destroyed circadian rhythms in both behavioral and endocrine outputs. Just 20 000 or so cells seemed to be responsible for controlling the timing of a mammal's endogenous rhythms. Support came from Bill Schwartz who decided to study the metabolism of the SCN. Schwartz injected 2-deoxyglucose (2DG) and found that the SCN is metabolically active during the light phase of a 12 h:12 h light–dark cycle and relatively inactive during the dark phase. Significantly, no other brain region showed such a dramatic rhythm.

By the middle of the 1980s, several laboratories had shown that circadian activity rhythms in SCN-lesioned adult rats and hamsters could be restored by transplanting fetal SCN. The final proof that the SCN contained the ''master clock'' came from the chance discovery of a mutant golden hamster in Michael Menaker's laboratory. Martin Ralph found that one of the hamsters in a routine shipment of animals had a circadian activity period of 22 h, which was far below anything seen before. This hamster was named the *tau* mutation, and subsequent breeding experiments showed that this was a single-gene defect and two alleles of the *tau* gene resulted in a 20-h circadian period. Ralph, Menaker, and colleagues then used these animals as a tool to see whether the SCN was indeed the key oscillator. They asked the critical question: If the SCN was taken from a 20-h mutant and transplanted into a wild-type SCN lesioned host, would the recipient show a circadian period of the donor (20 h) or of the recipient (24 h)? The results were unambiguous. In every case, the restored rhythm showed a period close to 20 h. Likewise, when the transplantation was done the other way round, from normal to mutant, again it was the period of the donor that was restored. This specificity of the period was the unambiguous proof

needed to satisfy even the severest skeptic. The hypothesis that the SCN contained a circadian oscillator was correct.

Soon after the *tau* mutant transplantation studies, other researchers found that even individual cells in the SCN show a circadian rhythm. A SCN was placed into culture and the individual cells were then dissociated from each other while supported on a multielectrode array. SCN neurons fire at a frequency between 0.3 and 9.9 Hz. However, the overall firing rate of the rat SCN neurons showed a marked circadian rhythmicity averaging 24.35 h, with peak rates of firing occurring during the subjective day. So, not only was the SCN the anatomical site of the oscillator but it was composed of individual cells that themselves oscillated and somehow co-coordinated their individual firing to give an overall rhythm. The hunt for the master circadian pacemaker of mammals dominated chronobiology for approximately 80 years, and establishing a central role for this structure represents one of the major achievements in the field. But as we shall discuss below, the view of a master clock within the mammalian SCN simply driving peripheral rhythmicity in physiology and behavior is an oversimplification. Other tissues possess the molecular components to generate a circadian oscillation independently of the SCN, and in many respects show patterns of gene expression that resemble the molecular clock of individual SCN cells. The uniqueness of the SCN, however, is that this tissue alone seems to be able to restore rhythmicity when transplanted into an SCN-lesioned host.

3.2.1 Entrainment

It was assumed that in humans and other mammals the same light-sensitive cells in the eye that are used for vision, the rods and cones, are also used to adjust the clock. But in the early 1990s, unexpected experimental results began to challenge this assumption. It had been known since the 1980s that the circadian system of mammals was relatively insensitive to light, needing both relatively bright and long duration exposure to light to bring about entrainment. For example, the visual system of a rodent is some 200 times more sensitive to light than the circadian system, and rodents will not entrain to a light stimulus shorter than 30 s. The human circadian system is more than a thousand times less responsive to light than our visual system, and again needs a long duration signal to entrain. It also became clear that there was a marked anatomical separation between the projections from the eye to the visual and circadian structures within the brain. The master circadian clock in mammals, the SCN (discussed below), receives its retinal projections from the RHT, which is formed from a small number of distinct retinal ganglion cells (RGCs). These RGCs (around 1% of the total) tend to be distributed evenly over the entire retina and send an unmapped or random projection to the SCN. By contrast, the ganglion cells of the visual system send a highly mapped projection to the visual centers of the brain, such that a point on the retina maps precisely to a group of cells in the visual cortex. The visual system is thus able to deduce both how much light and where it occurs in specific regions of the environment, whereas the SCN receives only information about the general brightness of environmental light. Thus, the mammalian eye has parallel outputs, providing both image and brightness information.

Eye loss (like constant darkness) results in free-running rhythms in all mammals studied, including humans. However, claims have been made from time to time that mammals have nonocular photoreceptors. There has even been a recent suggestion that humans have photoreceptors behind the knee, as bright light shone in this region apparently shifted human circadian rhythms. It was an amusing thought but unfortunately nobody could replicate the findings. All the experimental evidence shows that the circadian system of mammals is entrained exclusively via photoreceptors within the eye. Although ocular, the remarkable finding in recent years has been that neither the rods nor cones are needed for this task and there exists another photoreceptor within the eye. The identification of this nonrod, noncone ocular photoreceptor has resulted from a series of experiments over a 10-year period. The first experiments studied mutant mice that lacked all rod and most of their cone photoreceptors. This mutant strain of mouse, known as the *retinal degeneration* or *rd/rd* mouse, is visually blind. But despite the massive (but not complete) loss of their rods and cones, these animals showed normal circadian responses to light. Blocking light reaching the eye abolished entrainment, confirming that the photoreceptors were indeed located within the eye. At the very least, these studies in mice and later studies in other rodents and humans showed that the processing of light by the eye for vision was very different from the way the eye processes light information for the clock. However, suggestive as these early studies were, they did not conclusively demonstrate the existence of a new ocular photoreceptor. Although the rods and cones were massively reduced in these mammals, they were never completely eliminated. There was the possibility that even a small number of photoreceptors may still be sufficient to maintain normal circadian responses to light. As a result, a new model, the *rd/rd cl* mouse, was developed that lacked all its rods and cones. Remarkably, these mice still showed normal circadian responses to light. Again, by blocking light reaching the eye, the effects of light on the circadian system were abolished, so there had to be a novel ocular photoreceptor. Because these mice lacked an outer retina, the new photoreceptor cells were assumed to be located within the inner retina, and the search was on for these novel sensory cells using a range of different approaches.

The spectral responses or action spectra for adjusting the circadian clock of *rd/rd cl* mice demonstrated the involvement of an opsin/vitamin A–based photopigment with a λ_{max} of ~480 nm (OP^{480}). The known mouse photopigments peak at ~360 nm (UV cone), ~498 nm (rod), and ~508 nm (green cone) and do not show any significant fit to the 480-nm action spectrum in *rd/rd cl* mice. These results argued that a novel photopigment contributes to the regulation of circadian response to light in the mouse. Parallel studies in rodents showed that at least some of the retinal ganglion cells that project to the SCN are intrinsically light sensitive. This was demonstrated by recording from single RGCs from the normal rat retina either surgically or pharmacologically isolated from the rods and cone or by monitoring light-induced changes in calcium concentration in the RGCs of the whole retina from *rd/rd cl* mice. Significantly, these light-sensitive RGCs express the photopigment melanopsin. Evidence that melanopsin plays an important role in the transduction of light information in the intrinsically photosensitive RGCs comes from several sets of

experiments. The first set of experiments showed that melanopsin knockout mice have attenuated phase-shifting response to light and that the photosensitive RGCs fail to respond to light in these melanopsin knockout mice. Most recently, mice in which rods, cones, and melanopsin photoreceptors have all been ablated failed to show any responses to light, arguing that these three classes of photoreceptors account for all light detection within the eye. These data support the conclusion that unlike the cryptochromes of *Drosophila*, mammalian cryptochromes play no role in circadian photoreception (see Sect. 3.2.2). Indeed, Russell Van Gelder, at Washington University School of Medicine, who has been the main proponent for a photosensory role for the cryptochromes stated recently: ''It would thus appear that the primary photopigment in non-visual photoreception is melanopsin-dependent, but not cryptochrome-dependent.''

The light signal from these different photoreceptors is transmitted to the SCN by the RHT. Two neurotransmitters, glutamate and pituitary adenylate cyclase-activating polypeptide (PACAP) that are stored in the projections of the RHT signal the information. If glutamate is applied to the SCN, then it will mimic the effects of light, while substances that block the action of glutamate will block light-induced phase shifts of the clock. Light or glutamate will delay the clock in the early night by increasing the levels of calcium (Ca^{2+}) within SCN neurons. But during the late night, light or glutamate seems to act via a different signaling cascade to induce phase advances. PACAP seems to modulate the action of glutamate. The differential response of these neurotransmitters acting at the level of individual SCN neurons to light provides the molecular basis for the delay and advance portions of the PRC (Fig. 2). The light input pathway to the clock interacts with the circadian oscillator so as to synchronize it to the solar cycle. Understanding how this happens at the molecular level takes us to the heart of how the circadian clock is generated.

Establishing that there are photoreceptors other than the classic rods and cones also has practical applications. The studies in retinally degenerate mice encouraged studies of circadian function in blind people. Josephine Arendt and her group at the University of Surrey and Charles Czeisler's group at Harvard both identified blind individuals with eyes but who lacked conscious light perception. Despite this, some of these individuals were still able to regulate their circadian responses to light. One practical result is that every attempt is now made to preserve an intact eye in people suffering from certain forms of eye disease so that it can perform its circadian function.

3.2.2 **Oscillator**

Before we consider the complex nature of the molecular clock in mammals (Fig. 5), the key players will be formally introduced and have been summarized in Table 1. Forward and reverse genetics have been the approaches used to identify the components of the mammalian molecular clock. Forward genetics represents the classical approach for identifying gene function, as exemplified in *Drosophila*, which typically starts with an abnormal phenotype and attempts to isolate the gene responsible. By contrast, reverse genetics starts with a gene of interest (often due to homology) and investigates the effects of mutations or deletions. Forward genetic approaches in circadian biology were originally thought to be impossible in mammals due to the labor and animal-intensive nature of such screening programs. Put bluntly, the cost

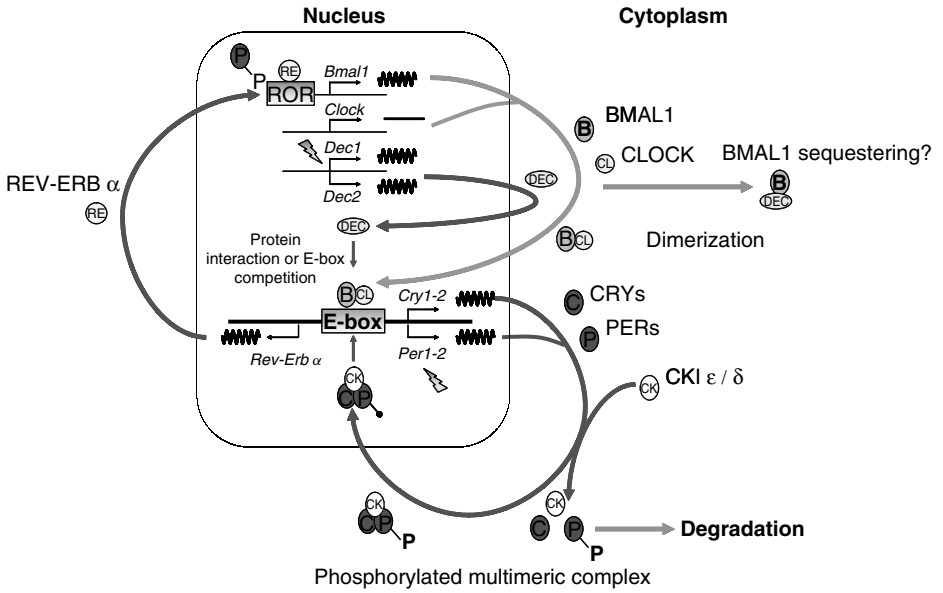

Fig. 5 The mammalian molecular clock is based upon a transcriptional drive produced by CLOCK:BMAL1 heterodimers. *Clock* is constitutively expressed, whereas *Bmal1* is rhythmically expressed. The CLOCK:BMAL1 heterodimers bind to E-box enhancers in the *period* and *cryptochrome* promoters, producing rhythmic *Per* and *Cry* expression. The resulting PER proteins are phosphorylated by CK1ε/δ and interact with CRY proteins to form a phosphorylated multimeric complex. This complex reenters the nucleus and produces a negative feedback by inhibiting CLOCK:BMAL1-mediated transcription. An additional loop is produced via *Rev-erbα*, which also possesses an E-box enhancer activated by CLOCK:BMAL1. *Rev-erbα* acts via an ROR element in the *Bmal1* promoter to inhibit *Bmal1* transcription, thus feeding back to remove the positive drive produced by CLOCK and BMAL1. As the PER/CRY/ CK1ε/δ complex reenters the nucleus and inhibits the CLOCK:BMAL1 drive on the E-box, *Rev-erbα* expression is also reduced. This leads to a disinhibition (activation) of *Bmal1*, thus restarting the molecular cycle. The newly identified components *Dec1* and *Dec2* may modulate the CLOCK:BMAL1 drive by competing for E-box binding or sequestering BMAL1.

and time required for such a mutagenesis screen seemed prohibitive. However, it was in fact a forward genetics approach that isolated the first clock gene (*Clock*) in mammals after the screening of only 25 animals! Despite this success, the majority of the mammalian *clock* genes have been identified using reverse genetic approaches. Mammalian homologs of the *Drosophila clock* genes (*mPer1–3* and *mCry1–2*) have highlighted a remarkable conservation of clock components between insects and mammals (due to the similarities found between species, where necessary we shall use the prefix "d" to indicate *Drosophila*, "m" to indicate mouse, "h" to indicate human and "zf" to indicate zebrafish). In addition, the use of interaction screens with previously identified clock components has been essential in identifying further elements involved in the mammalian clock (*Bmal1, Rev-Erbα, Dec1,* and *Dec2*). Common features of many of the proteins involved in the mammalian oscillator are bHLH motifs and PAS domains. As discussed

Tab. 1 Table depicting the peak expression of both mRNA and protein of the major components of the mammal (mouse) molecular clock. Time of day and the relative light–dark cycle are indicated. The approximate peaks of mRNA and protein are shown in light and dark gray respectively. The method of identification has been listed as either homology to *Drosophila*; interaction screens with previously identified clock proteins; or reverse genetics employing mutational screening. The impact of specific gene mutations upon the circadian phenotype is shown along with the free-running period (τ)

	SCN expression profile	Isolation & Analysis	Mutation	
Time	1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24	Identification	Phenotype	τ

*Asterisks indicate genes that are upregulated by light.

above (Sect. 3.1.2), bHLH motifs occur in a variety of proteins capable of binding DNA, while PAS domains are amino acid sequences involved in protein:protein dimerization.

The first clock gene to be isolated in mammals was named *Circadian Locomotor Output Cycles Kaput*, or less torturously *Clock*, by using chemical mutagenesis coupled with a screen for abnormal circadian phenotypes. The *Clock* mutation results in a lengthened free-running period, and in homozygous mutants, a loss of circadian rhythms after several days in constant darkness. By use of positional cloning and transgenic BAC rescue, *Clock* was characterized. The *Clock* gene is a large transcriptional unit of around 100 000 bp, with 24 exons, encoding an 855 amino acid bHLH PAS domain–containing protein. *Clock* mRNA is widely expressed throughout the brain, with highest levels found in the SCN and pyriform cortex. The mutant *Clock* allele possesses a truncation of its transcriptional activation domain, providing a molecular basis for its loss of function. In addition, overexpression of *Clock* can lead to a period shortening. The expression of *Clock* mRNA appears to be nonrhythmic within the SCN, although recent studies have suggested that *Clock* mRNA may be weakly rhythmic.

The search for a binding partner for CLOCK was facilitated by the identification of additional bHLH PAS proteins, including Brain muscle arnt-like 1 (BMAL1) and five additional members of the PAS superfamily (MOPs 1–5). BMAL1 (MOP3) was independently identified in screens for bHLH PAS proteins involved in dioxin-signaling pathways and central nervous system development, and its importance to circadian rhythmicity was not initially appreciated. A series of clever molecular screens demonstrated that BMAL1 is capable of forming transcriptionally active complexes with CLOCK, which specifically bind E-box enhancers. From studies in *Drosophila*, E-box enhancers were known to be important in driving expression of *dper* and were also found to be present in the mammalian homolog (see below). In addition, the previously identified mutant CLOCK protein was found to be capable of dimerizing with BMAL1 and binding DNA, but failed to activate *dper* transcription. The importance of BMAL1 in the clock mechanism was highlighted when targeted deletion of this gene was found to result in an immediate loss of behavioral rhythms in constant darkness and reduced activity under normal light–dark cycles. *Bmal1* mRNA is expressed in the SCN in antiphase to the *Period* and *Cryptochrome* genes (see below), with a peak expression around CT 18. BMAL1 protein also appears to be rhythmic, with a peak expression between CT 0 and 8.

The identification of the mammalian *Period* (*Per*) genes followed closely on the heels of *Clock*. The presence of a mammalian homolog of the *Drosophila per* gene was suggested by an early study, demonstrating staining of the SCN with a *Drosophila* PER antibody. However, the isolation of the mammalian *Per* gene was not reported until 1997, when two groups independently isolated human and mouse sequences. The *Per* (or *Rigui* as it was alternatively named) gene encodes a PAS domain–containing protein with 44% homology to *Drosophila per*. *mPer* is expressed in a circadian manner within the SCN under constant conditions, and peaks ~CT 4–6 under a light–dark cycle. In addition to *Per* (hereafter termed *Per1*), further homologs were soon identified and named *Per2* and *Per3*, respectively. An additional *Per* gene, *Per4* was also isolated

in humans, although this appeared to be a pseudogene caused by retrotransposition of an ancestral *Per3*, as it contains no introns and numerous insertions, deletions, and frame shifts. The PER proteins all possess PAS domains, but do not appear to be capable of DNA binding. All three *Per* genes are rhythmically expressed in the SCN, with *Per1* and *Per3* peaking around CT 4–6 and *Per2* slightly later at CT 9–12 (see Table 1). *In vitro*, all appear capable of modestly inhibiting the CLOCK:BMAL1 transcriptional drive. However, *in vivo*, this negative feedback appears much reduced. The *Per1* and *Per2* genes play an essential role in the clock mechanism, as simultaneous deletions of both genes result in arrhythmicity. *Per1* and *Per2* also appear important in the light input to the molecular clock. In the SCN, both genes show increased expression following a nocturnal light pulse.

Targeted deletion of the *mPer1* gene results in a shortening of circadian period by around an hour, with reduced precision and stability of the cycle. However, in extended periods of constant darkness, *mPer1* knockouts become arrhythmic. The phase-shifting ability of *mPer1* mutants appears normal, and induction of *c-fos* in the SCN in response to light is no different to wild-type animals. Furthermore, deletion of *mPer1* does not appear to alter the molecular phenotype, as rhythms of *mPer2, mCry1,* and *Bmal1* are unaffected. Mice homozygous for a mutation of the *mPer2* gene arising from a deletion of 87 residues of the PAS domain ($mPer2^{Brdm1}$) exhibit a shorter free-running period, followed by a loss of rhythmicity in DD. The molecular phenotype of these animals is surprising, as *mPer1* and *mCry1* mRNA levels are still rhythmic in the SCN in DD, although the amplitude of expression is reduced. Furthermore, the peak expression of *Bmal1* is shifted, suggesting that *mPer2* may in fact play a role in a positive feedback mechanism. Levels of mPER2 protein are also reduced in *mCry*-deficient animals, even though *mPer2* mRNA is expressed at constant mid- to high-range levels, suggesting that mCRY proteins may be important for the stabilization of mPER2. The mechanism of the positive drive of mPER2 on *Bmal1* remains unclear, but may involve driving *Bmal1* transcription when *Rev-Erbα* is inhibited.

Mice with a targeted disruption of *mPer3* present a more subtle circadian phenotype than their *mPer1* and *mPer2* counterparts. The circadian period of these animals is shortened but maintained in DD, and the expression of other clock genes appears largely unaffected. Moreover, double mutants of *mPer1/mPer3* and *mPer2/mPer3* display the same phenotype as single *mPer1* and *mPer2* mutants, respectively. This has led to the suggestion that *mPer3* may in fact be involved in the output of the clock, rather than as part of the central mechanism.

The two mammalian *Cryptochrome* genes (*Cry1* and *Cry2*) were originally isolated through their homology with *Drosophila* (6–4) photolyase and plant cryptochromes.Owing to their homology with plant and *Drosophila* cryptochromes, it was not long before the *Crys* were suggested to be involved in mediating the light input to the circadian system. However, in mammals, the evidence for this was always weak, and recent studies have shown that the CRYs do not contribute to circadian light detection. Expression of *Cry1* mRNA in the SCN is rhythmic, whereas results on *Cry2* have suggested either no rhythmicity or weak rhythmicity within the SCN.

The peak of CRY1 protein expression follows some 2–3 h after the mRNA peak. Evidence for an involvement of *Crys* in the molecular clock emerged following targeted deletion studies, where *mCry1* knockouts were found to have a free-running period approximately 1 h shorter than wild-type animals. In contrast, *mCry2* knockouts exhibited a period of approximately 1 h longer. The most surprising result of these studies was that double *mCry* knockouts were totally arrhythmic in DD, suggesting that the mCRYs play an essential role in the molecular oscillator. In the double *mCry* knockouts, levels of *mPer1* mRNA in the SCN were found to be constitutively high and nonrhythmic, whereas *mPer2* levels were rhythmic under LD but showed constitutive mid-level expression in DD. These data suggested that the negative limb of the molecular clock in mCRY knockouts had been disrupted. This was confirmed by *in vitro* studies, which demonstrated that both CRY proteins were capable of inhibiting CLOCK:BMAL1 mediated transcription.

An additional component of the mammalian molecular clock was provided by the analysis of the *tau* mutation (see Sect. 3.2). The absence of genetic resources for the hamster proved a major setback in identifying the molecular basis of the *tau* mutation. However, by using a region of conserved synteny to the human and mouse genomes, the *tau* locus was shown to encode casein kinase 1ε (CK1ε), a serine/threonine protein kinase, and a mammalian ortholog of *Drosophila doubletime* (*dbt*). The *tau* mutation results in a nonconserved substitution at residue 178, resulting in an enzyme that can bind PER1 and PER2, but has a decreased ability to phosphorylate these proteins. The isolation of CK1ε also led to the identification of CK1δ as a candidate clock regulator. This protein has 76% identity to CK1ε, and will also bind and phosphorylate PER1 *in vitro*. CK1ε lacks any rhythmic expression either at the mRNA or protein level.

Despite the isolation of a mammalian ortholog of *Drosophila timeless* early on in the dissection of the mammalian clock, a role for *mTim* and its protein product in the circadian mechanism remains uncertain. Expression of *mTim* is not rhythmic, nor is it light induced. Targeted disruption of *mTim* results in a normal circadian phenotype in heterozygotes, but homozygous deletion is embryonic lethal. A twist in the *Timeless* tale has come to light, however, as the *mTim* originally isolated appears not to be the true ortholog of *Drosophila tim* but instead is the ortholog of a more recently described gene, *time-out* (Sect. 3.1.3). A true mammalian ortholog of *dtim* may therefore exist, and a role within the circadian mechanism cannot be excluded.

Genome-wide complex trait analysis has suggested that in addition to those genes already identified, numerous uncharacterized loci contribute to the genetic complexity underlying the circadian phenotype. Vital pieces of the clock puzzle are undoubtedly missing and at the time of writing this review, the most promising candidates were *Rev-Erbα* and *Dec1* and *Dec2*. The nuclear orphan receptor *Rev-Erbα* is a transcription factor that binds to retinoic acid receptor-related orphan receptor (ROR) elements in the 5′ promoter of *Bmal1* to inhibit its expression. *Rev-Erbα* was isolated by analysis of the *Bmal1* promoter for known transcription factors and independently by screening transcription factor binding sites in genes shown to be rhythmic by microarray analysis. *Rev-Erbα* is expressed in a circadian manner, and knockouts display reduced

amplitude rhythms of both *Clock* and *Bmal1*. Despite these effects, constant conditions do not result in arrhythmicity in these animals. However, the free-running period is slightly shorter in knockouts, and light pulses produce dramatically increased phase shifts. DEC1 and DEC2 are additional bHLH proteins that appear to either directly interact with BMAL1 or compete for E-box binding, and thus modulate the positive drive of the clock. *Dec1* and *Dec2* are expressed in the SCN in a circadian manner, and the expression of *Dec1* is induced by light during the subjective night. By contrast, *Dec2* is unresponsive to light stimuli. The precise role played by these factors in the circadian clock *in vivo* remains to be clarified, and the effects of targeted deletion of the *Dec* genes is unknown. Another PAS domain protein that has attracted attention is the neuronal PAS-2 protein (NPAS2), also known as MOP4. However, NPAS2 is not expressed in either the adult or neonatal SCN and as such does not appear to be involved in the core clock mechanism. NPAS2 has recently been suggested to play a role in hormone-mediated regulation of peripheral vascular clocks, where it shows robust rhythmic expression. Furthermore, DNA binding by NPAS2 appears, *in vitro*, to be regulated by both redox state and cellular gas concentration (e.g. CO_2) via interactions with heme.

As can be seen, the mammalian molecular clock appears to be the emergent product of multiple interacting transcriptional–translational feedback loops, comprising both positive and negative elements. Studies in *Drosophila* have provided an essential framework for the understanding of the mammalian clock, allowing the assembly of genetic networks of ever-increasing complexity. The following is an attempt to summarize a current model of how all these interactions fit together to yield the molecular mechanism that enables the mammalian clock to tick (see Table 1 and Fig. 5).

The driving force of the mammalian oscillator appears to be the rhythmic transcriptional enhancement provided by CLOCK:BMAL1 heterodimers. *Bmal1* transcription yields rhythmic BMAL1 protein that heterodimerizes with constitutively expressed CLOCK. The CLOCK:BMAL1 complex binds to E-box enhancers, driving rhythmic transcription of the *Per 1–3* and *Cry 1–2* genes. The PER and CRY proteins form homo- and heterodimers and translocate back to the nucleus, where CRY forms the negative limb of the clock by interacting with CLOCK and/or BMAL1 to inhibit *Per* and *Cry* transcription. A positive drive also occurs, and indeed, may be an essential component for sustained rhythmicity, providing the instability required for sustained oscillations. PER2 has been suggested to provide a positive drive on *Bmal1* transcription, and *in vitro* assays have revealed that transcription of *Bmal1* is enhanced by both CRYs and PER2, but is repressed by CLOCK:BMAL1, suggesting the presence of both positive and negative drives on *Bmal1* transcription. These findings can be explained, at least in part, by the action of the recently identified nuclear orphan receptor *Rev-Erbα* (Fig. 5). As well as driving the expression of PERs and CRYs, CLOCK:BMAL1 also enhance expression of *Rev-Erbα* via an E-box, and, thus, REV-ERBα protein synthesis. REV-ERBα then feeds back to inhibit *Bmal1* transcription by acting through ROR response elements in the *Bmal1* promoter. The inhibition produced by REV-ERBα is removed by the CRY negative feedback loop on the CLOCK:BMAL1 heterodimer, which leads to a disinhibition (activation) of *Bmal1*. The central drive of the clock may

in turn be modulated by DEC1 and DEC2, as these proteins are capable of inhibiting CLOCK:BMAL1 mediated transcriptional activation *in vitro*, through either direct protein–protein interactions or competition for E-box binding. An additional level of regulation has also been suggested on the basis of independent evening (E) and morning (M) oscillators. The evidence for this model stems from the differing roles of *Per* and *Cry* genes within the clock and the differences in light responses and control of output pathways at different times of the circadian cycle.

While translational delays are expected to occur between mRNA and protein synthesis (especially with posttranscriptional modification of large polyintronic mRNAs), these delays by themselves appear insufficient to provide a cycle of 24 h. The discovery of a range of posttranslational mechanisms that affect nuclear entry, protein interactions, phosphorylation states, and degradation of the clock proteins will all build time delays into the molecular mechanism to produce the 24-h output. For example, as the mutation in Ck1ε in the *tau* mutant hamster results in a shortened circadian period, and diminished rate of phophorylation of PER *in vitro*, phosphorylation has been proposed as one mechanism for providing time delays. However, this view would not be supported by *in vivo* data from the *tau* mutant, which shows that the degree of PER phosphorylation is unaffected. Nevertheless, phosphorylation does appear to be critically important. The degree of phosphorylation of PER has been shown to affect its cytoplasmic retention, possibly by masking nuclear localization signals. Furthermore, the half-life of human PER1 is reduced by phosphorylation, and phosphorylation of PER1 and PER3 by CK1 results in rapid degradation via the ubiquitin-proteasome pathway.

In the context of protein–protein interactions and the generation of the circadian period, heterodimerization of CRY and PER appears essential for nuclear translocation. *Cry* double knockouts have lower levels of the PER1, PER2, and CK1ε in the nucleus (Fig. 5). The formation of PER:CRY heterodimers also appears to be important for preventing the breakdown of PER2 by the ubiquitin-proteasome pathway. As well as PER:CRY heterodimers, PER proteins will dimerize with each other as well as with CK1ε. PER proteins may act as a scaffold to enable the simultaneous binding of CRYs and CK1ε, and the phosphorylation of CRY is dependent upon both proteins being bound to PER. The absolute levels of CRY and CK1ε protein are in excess of PER, suggesting that PER abundance is normally rate limiting for PER:CRY heterodimerization, which is in turn necessary for nuclear entry of the protein complex (Fig. 5). Further evidence for the role of PER in nuclear localization comes from the subcellular localization of CRY proteins in PER1/PER2 double mutants. In these animals, CRY was concentrated in the cytoplasm, but only weakly detectable in the nucleus. Furthermore, the synchronous nuclear localization of PERs, CRYs, and CK1ε appears to be dependent upon PER rhythmicity. The circadian variation in protein interactions results in phosphorylated multimeric complexes of PER, CRY, and CK1ε in the nucleus, which are bound to DNA during the negative feedback phase of the molecular cycle. Despite the rhythmic expression of BMAL1 protein, CLOCK:BMAL1 heterodimers are bound to DNA throughout the circadian cycle. Thus, it is the rhythmic presence of the phosphorylated multimeric complex

that appears to inhibit the CLOCK:BMAL1 transcriptional drive.

Cellular metabolism may also be linked with the clock mechanism. *In vitro*, the DNA binding activity of BMAL1:CLOCK and BMAL1:NPAS2 heterodimers are regulated by the redox state of the respiratory chain electron carrier nicotinamide adenine nucleotide (NAD). The reduced form, NADPH, stimulates DNA binding, whereas the oxidized form, $NADP^+$, inhibits DNA binding. Consequently, the NADPH:$NADP^+$ ratio, which is affected by the metabolic state of the cell, may act to influence the central drive to the circadian clock. Evidence for such a role *in vivo* is, however, lacking and given the presence of CLOCK:BMAL1 heterodimers bound to DNA throughout the circadian cycle may not play a major role.

3.2.3 Output

While a quantum leap has occurred over the last decade in our understanding of the inputs and mechanisms of the mammalian circadian system, the links between these cellular oscillators and overt behavioral rhythms, while undeniably present, still remain poorly understood. In short, how does the SCN transduce rhythmicity to the rest of the animal? Although direct neural projections from the SCN to target brain regions have been demonstrated, factors secreted from the SCN play a critical role. A role for humoral signals in SCN output was suggested following the functional rescue of circadian rhythms in SCN-lesioned animals by transplantation of SCN tissue from mutant animals (see Sect. 3.2). These transplants were encapsulated in a semipermeable membrane to prevent neural outgrowth, therefore demonstrating that the factor(s) responsible for rhythmicity were humoral in origin. Two neuropeptides, transforming growth factor α (TGFα) and prokinectin-2 (PK2) have been recently isolated, and form strong candidates for providing this humoral signal.

A number of microarray studies have recently highlighted the extent of circadian regulation of the transcriptome in a variety of tissues, including liver, heart, SCN as well as fibroblasts, with estimates varying from 3 to 9% of genes demonstrating circadian modulation. What we know is that within the SCN, several first-order clock-controlled genes (ccg) have been identified that appear to play a role in transducing the output signal from the molecular oscillator to effector systems. Moreover, several of these genes appear to be involved in similar roles in peripheral clocks. Both mRNA and protein levels of the neuropeptide arginine vasopressin (AVP) display robust circadian rhythms. The rhythmic expression of AVP appears to be a product of BMAL1:CLOCK binding to an E-box enhancer within its promoter. Vasopressin acts locally to regulate the amplitude of SCN firing, as well as transmitting circadian signals to other hypothalamic targets. D-element binding protein (DBP) is a bZIP transcription factor, also driven by BMAL1:CLOCK E-box binding. DBP has been shown to regulate key enzymes in metabolic processes within the liver, and may play a similar role in regulating second-order clock-controlled genes in the SCN.

While early studies recognized the expression of clock genes outside of the SCN, the finding was typically overlooked because of the essential role of the SCN in providing rhythmicity. After all, SCN-lesioned animals are arrhythmic! However, it has become clear over the last few years that the broad expression patterns of the clock genes appear to

truly reflect oscillatory mechanisms that are independent of the SCN. The field of chronobiology was truly shocked when in 1998, Uli Schibler at the University of Geneva found that a cell line of fibroblasts that had been cultured for about 30 years could be induced to show a 24-h pattern of clock gene expression. He was able to induce 24-h cycles of expression by simply treating the cultured cells with serum. Somehow, one of the many ingredients in the serum (or a combination) was capable of initiating a 24-h oscillation of clock gene expression for a few cycles before the oscillation flattened and damped out. The rhythm could be induced once again with a further exposure to serum.

The possibility of peripheral oscillators in mammals made sense of a range of somewhat anomalous findings. Early studies had shown that when food was available only for a limited time each day, rats increased their locomotor activity 2 to 4 h before the onset of food availability and will even behave this way after their SCN had been lesioned. Recent work in Mike Menaker's laboratory has shown that circadian rhythms of clock genes within the liver can function independently of both the SCN and the light–dark cycle. Providing food for a 4-h period in the middle of the rat's subjective day had little effect on its general nocturnal behavior, but it showed increased locomotor and clock gene expression in the period before feeding. This suggests that food intake in itself generates an entraining signal for the liver and perhaps other digestive organs. The research team suggests that ''the hierarchical method is still at least partially valid: the SCN does generate rhythmic neural and hormonal signals that influence rhythms in other brain areas, in peripheral endocrine organs such as the pineal and in behavior. Nevertheless, circadian oscillations in the liver (and perhaps in other peripheral organs) may respond more directly to the environment. This revised view of mammalian circadian organization emphasizes the possible role of behavior in maintaining internal temporal structure''.

The view of the circadian system in mammals has changed from a central clock driving all outputs to a hierarchy of multiple oscillators, including tissues such as the liver, heart, spleen, kidney, lung, and testes. As such, the differences between central and peripheral oscillators have remained difficult to clarify, and synchronization of these oscillators may represent an inevitable consequence of multiple oscillatory phenomena, whereby any stimuli capable of transferring temporal information from one oscillator to another may function as a potential zeitgeber. The importance of the SCN may simply reflect its privileged position of receiving light input from the retina and its ability to modulate peripheral rhythms directly via hormonal and autonomic outputs as well as indirectly through driving locomotor activity (Fig. 2). Eighty years after Richter started to study endogenous activity in the rat, we return to one of his central themes. He showed that an animal maintains its internal stability through its general behavior as well as through specific and automatic physiological processes. The recent studies on food restriction and liver activity suggest that there is a possible role for behavior in maintaining internal temporal structure. Thus, models for circadian organization in mammals should include feedback loops from outputs, such as feeding, which may act as zeitgeber signals to assist in the overall regulation of the circadian system.

3.3 Zebrafish

At present, zebrafish represent the only alternative vertebrate genetic model to the mouse. To phrase this differently, there are only two model systems currently available in vertebrates, in which one can perform a forward genetic or mutant screening–based approach for determining the genes involved in a biological problem. The zebrafish system certainly is not nearly as advanced in genetic terms as the mouse or *Drosophila*, but progress is being rapidly made by research institutes such as the Sanger Center in terms of sequencing the genome.

Zebrafish made a relatively late arrival on the circadian scene. Consequently, relatively little is known in explicit detail about clock entrainment, central mechanism, or the output processes. However, the fish system has provided interesting novel information on developmental aspects of the circadian clock (developmental biology of course being one of its main applications) and surprising data regarding clock organization at the whole animal level.

The cloning of a zebrafish homolog of the *Clock* gene followed shortly after the identification of this gene in the mouse. Not surprisingly, the initial efforts examining the expression profile of this gene focused on the eye and the pineal gland, the two structures known in the lower vertebrates to contain a circadian clock. Of some interest was the finding that transcript levels for *zfClock* showed a robust circadian oscillation, something that is lacking for the mRNA of *mClock* in the SCN. Control studies were performed on other tissues, which we believed lacked a pacemaker, with the certainty that no clock expression or at least no rhythm would be detected. It generated considerable surprise, therefore, when a robust rhythm was detected in these body tissues, which included the samples taken from whole brain, heart, kidney, gill, fin, and so on. This raised two possibilities (1) that these peripheral oscillations are driven by a central master circadian clock or (2) that each tissue within the animal contains an independent, endogenous circadian pacemaker. To test this, a simple tissue culture procedure was established and organs such as heart and kidney were cultured for multiple days. The results from these culture experiments revealed a damped but continuing circadian oscillation in *clock* gene expression. Each organ in the fish must, therefore, contain its own circadian clock. Additional studies using primary cell lines generated from 24-h zebrafish embryos revealed similar oscillations. The current view is that most, if not all, cells within the zebrafish body contain a functional circadian clock. In this regard, zebrafish bears considerable similarity to data previously described in *Drosophila* and the emerging results from mammals. An obvious but central question is, how are these peripheral and cell line clocks set to local time? This issue is discussed below.

3.3.1 Entrainment

How are these tissue and cell clocks entrained? The simplest hypothesis was that these peripheral clocks would be set by some form of hormonal cue secreted by a ''master'' clock (possibly a pineal or retinal pacemaker), and as such this hormonal signal would maintain internal synchrony. One might postulate that such a signal could be melatonin, or possibly even a glucocorticoid hormone. However, the reality is a little more bizarre. A group of dissected zebrafish hearts was placed

into illuminated incubators on either a matching light cycle to the individuals from which they were removed (LD cycle) or on a reversed (DL cycle). By examining the levels of clock gene expression over the next 5 days in culture, it became clear that the circadian clocks within these hearts re-entrained to the reversed light cycle very rapidly, in fact within two cycles of exposure to the new lighting regime. This result has also been seen with other zebrafish tissues, as well as cell lines. The organs and tissue within the fish not only contain a clock but are also directly light responsive. All of these cells must, therefore, contain the relevant circadian photopigments and signal transduction pathways to enable this completely decentralized form of clock entrainment.

The obvious question of course is, what are these tissue photopigments and signaling events? The answer is not yet clear, but some candidate molecules have been proposed. The groups of Sancar and Sassone-Corsi performed an action spectrum on a zebrafish embryonic cell line in an attempt to determine optimal wavelengths for clock gene induction. Only one wavelength produced a significant response at 380 nm. On the basis of this single peak in the UV/blue wavelengths, it has been proposed that the relevant photopigment is not an opsin but in fact a cryptochrome. Cryptochromes have of course been implicated in *Drosophila* entrainment as discussed earlier (Sect. 3.1.1). In reality, the shape of this action spectrum neither fits that predicted for an opsin or a cryptochrome. The fact that these experiments were performed on cells in suspension (zebrafish cell lines grow as attached cells) and using RNase protections as a means of assaying RNA levels, which works badly at submaximal light intensities, raises some concerns regarding the validity of these data.

Cryptochromes are certainly expressed throughout most tissues in zebrafish, but as they are likely to play a central role in the core clock mechanism, this cannot be used as an argument for their role in light detection. There are six cryptochromes in the zebrafish, and the role of this class of molecule is likely to be quite complex. The isolation and identification of a widely expressed opsin, however, does generate a novel candidate for the role of a circadian photopigment. The Foster group identified a novel class of opsin by screening a *Fugu* (pufferfish) gridded genomic cosmid DNA library with a probe designed against Salmon VA opsin. The resulting novel opsin gene has been called *Teleost Multiple Tissue* opsin or TMT opsin, and is unique, in part, due to its unusual expression profile. Unlike most opsins, which are expressed primarily in the retina, pineal gland, or a few highly localized photoreceptive brain regions, TMT opsin is found throughout adult brain, in tissues such as heart and kidney, and in clock-containing embryonic cell lines, but not in cell lines lacking a clock. In other words, the expression pattern of this opsin parallels the localization of directly light-entrainable clocks. Though, of course, this correlation cannot be taken as proof of function (such studies are underway), TMT opsin is certainly the best candidate to date for the role of zebrafish circadian photopigment.

The signaling events that link the photopigment to the circadian clock are also not well elucidated. A possible role for the MAP kinase pathway has been proposed, but again no convincing functional tests of this pathway have yet been conducted. The potential roles of CREB and its phosphorylation, or the induction of *c-fos*

transcription, as seen in the SCN of mammals have not been examined. Nor has the role of intracellular calcium changes been explored to date; but this work is currently underway. One can reasonably state that, at this time, there are more question marks than candidates on the zebrafish input or light-signaling pathway.

3.3.2 Oscillator

Again, owing to the recent arrival of zebrafish on the circadian scene, not a great deal is known about the central clock mechanism. This fact, though, is certain to change in the near future, and a number of laboratories have isolated circadian clock mutant animals. When the genes mutated in these animals have been identified, it is likely that novel clock components will be discovered. The availability of numerous clock-containing, light-responsive primary cell lines in the zebrafish, which are not available in any other animal model, will also aid greatly in the functional testing and biochemical analysis of how these clock components fit together.

To date, all of the known clock genes in zebrafish have been cloned by homology from *Drosophila* and mouse. The first zebrafish clock gene to be cloned was *zfClock*, the zebrafish homolog of the first vertebrate clock gene, *mClock*. There was considerable similarity between the two genes, both possessing two distinct PAS domains, a DNA binding domain, and an extremely long glutamine-rich transactivation domain in the C-terminus of the protein. The major and most interesting difference between zebrafish and mouse *Clock* was the strong circadian rhythm seen in *zfClock* expression. Zebrafish *clock* shows a large peak in expression in the early night, whereas mouse *Clock* does not appear to oscillate, at least at the mRNA level.

The existence of two PAS domains suggested that *clock* had a protein partner that acted as a dimer within the cell. A yeast two-hybrid screen was, therefore, performed with zfCLOCK to identify novel partners. This screen yielded two interacting proteins, both very similar in sequence to each other and to the protein BMAL1. BMAL1 in mouse had also just been identified as a partner of the CLOCK protein in the mammalian system, and so perhaps it was no surprise that zebrafish were similar to mouse in this respect. The two *BMAL1* genes in zebrafish show a slightly different phasing, that is, timing of peak expression relative to the light–dark cycle, but the biological meaning of this is not yet clear. The CLOCK:BMAL1 dimer acts as a positive transcription regulator, activating the transcription of target genes via (generally speaking) E-box elements found in the promoter regions of these genes. The positive element of the circadian feedback loop, as represented by the action of CLOCK and BMAL, appears to be conserved between *Drosophila*, mouse, and zebrafish.

Over the last two years, the issue of genome duplication has arisen in the context of the zebrafish circadian system. This has been an issue in the area of zebrafish development, in particular, regarding *hox* gene duplication. It is clear that at some point in evolution zebrafish underwent a duplication of the genome in some areas, if not all, leading to a state of polyploidy. So, for example, three *Clock* genes and three *bmal1* genes have now been identified in zebrafish. There are also at least, but undoubtedly more than, three *per* genes. However, the greatest increase in gene number, as mentioned above, can be seen with the cryptochromes, of which there are currently six known distinct forms. Such genome multiplications have

been described in *Xenopus laevis*, and in this system, there is some evidence that the gene replication simply leads to the production of redundant copies. Do these multiple gene copies in zebrafish simply reflect redundancy in the clock mechanism? Though there is no absolute answer yet, the evidence suggests that these multiple genes are not simply redundant copies or pseudogenes as in the case of *hPer4* (see Sect. 3.2.2). In the case of the cryptochromes, different individual types show differences in the timing of their expression, as well as differences in the nature of their light induction. Similar differences exist for the *bmal1* genes, as described above, but this is also true for the *per* genes. Each of these gene replications appears to have had sufficient ''evolutionary time'' to have evolved distinct circadian characteristics. If these differences also reflect distinct functional roles, then the clock in fish may be appallingly complex, and one might be able to say that 15 clock genes have been identified to date in this species. Providing functional evidence for each of these genes will be quite a challenge. As a result, attempts to provide a model of the zebrafish molecular clock would be premature.

3.3.3 Output

With circadian clocks present in apparently most, if not all, tissues and cells, an obvious question is what are all of these tissue clocks regulating? At present, very few rhythmic clock output genes have been identified in the fish, although it is likely that there will be broad similarity between clock-controlled genes in mouse and zebrafish peripheral tissues. As discussed above, a wide range of cellular processes are regulated by the clock in tissues such as the mouse liver, including genes related to steroid biosynthesis, structural genes, glycolysis, and metabolism. One aspect of these mammalian studies, which take advantage of DNA microarray technologies, is that these organs are dissected and immediately processed for RNA at particular circadian times. In other words, the oscillations in gene expression seen in these tissues are occurring *in vivo* in the living whole animal. These data are, of course, of considerable interest, but from such studies it is not possible to determine whether these downstream oscillations are the result of peripheral clock control or central SCN clock control via neuronal or humoral regulation. The zebrafish should prove to be an excellent model system for the separation of local clock-controlled genes from those that might be regulated by a central master pacemaker. Such studies will be greatly facilitated by the relative ease with which it is possible to maintain zebrafish tissues in culture for many days. Oscillations in clock-controlled genes can then be compared between *in vitro* and *in vivo* samples, and some determination of the relative roles played by central versus peripheral clocks in regulating animal physiology can be ascertained.

One clear aspect of physiology under clock control, however, is the pineal and retinal release of melatonin. The clock regulation of these events appears to occur very early in development. The pineal gland is one of the first structures to differentiate in the developing zebrafish embryo, and is clearly present 26 h postfertilization. The first release of melatonin can also be detected at this time. Whether this early developmental production of melatonin has any impact on development has not explicitly been examined. However, it is likely that this hormone may play a role in pigmentation changes (and subsequent camouflage) in early larvae,

which are prone to high levels of predation during the initial stages of life.

Rhythmic locomotor activity is the standard measure of clock output. Zebrafish larvae have been video monitored and do show circadian rhythms in twitching movements or rotation within the chorion (egg) and so a clock does seem to regulate at least this aspect of rhythmic behavior. Adult fish are a little less reliable, with most animals being day active. However, some 73% of individuals are rhythmic in constant darkness at 21 °C. This level of noise in the behavior has made adult locomotor activity a relatively poor assay of clock function and, therefore, an undesirable method for identifying clock mutants. The level of adult activity does, however, seem to be very dependent upon the level of nutrition, and varies between fish facilities. Fish in certain animal facilities appear more circadian in terms of day/night activity than individuals maintained under different conditions.
